# Ammonia

## Hydronitrogen Compounds

*Encyclopedia of Liquid Fuels*, contains six chapters dealing with hydronitrogen compounds and four chapters dealing with hydrazines. “Ammonia” is the simplest hydronitrogen. The chapter “Hydrazine” deals with the parent inorganic compound hydrazine, while “Alkylhydrazines” deals with alkylhydrazines other than methylhydrazine and dimethylhydrazines, which are covered in the chapters “Methylhydrazine” and “Dimethylhydrazines,” respectively. Amines, amides, and imides are not counted as hydronitrogen compounds, although many of them contain N–H bonds.

### 1 Ammonia

Ammonia,  $\text{NH}_3$ , also known as nitrogen hydride, azane, CAS RN [7664-41-7], is a colorless gas at room temperature, with a pungent, lacrimatory odor. In an equestrian and agricultural setting, the ammonia concentration in horse stables resulting from the decomposition of urea in urine may be high enough to cause eyes to lacrimate and break out in tears. Ammonia dissolves quite rapidly in water. For laboratory and household use, ammonia is used as an aqueous solution. Reagent grade aqueous ammonia solutions (“*aqua ammonia*” in Latin) for chemical laboratory use usually contain 30 mass-%  $\text{NH}_3$  whereas household ammonia solutions, often used for window cleaning, contain only 10%  $\text{NH}_3$ . In either case, any ammonia solutions above 3%  $\text{NH}_3$  are hazardous and eye and skin contact must be avoided.

The most economic method to transport ammonia from production sites to end-use locations is in the anhydrous form as a liquid under its own vapor pressure. Anhydrous ammonia is evaporated and circulated in closed loops in commercial refrigeration units (cold-storage warehouses), where its high heat of evaporation results in efficient refrigeration cycles. Anhydrous ammonia was used as a rocket propellant fuel in the X-15 high-altitude-research rocket plane.

Ammonia intended for use as fertilizer is often transported through pipelines and by railroad cars and tanker trucks in the anhydrous liquid state under pressure and then diluted with water at the point of end use. Depending on soil and crop types, it can be used as a gas or dissolved in water. It can be injected into the soil in gaseous form (depending on the moisture content of the soil) or as an aqueous solution. Much ammonia is converted by the chemical industry into nitric acid, also often used in fertilizer production in the form of ammonium nitrate, an oxidizer which is based on ammonia as a feedstock [1].

Liquid and vaporized ammonia has been used in satellites as the working fluid for resistojets and arc jets.

Besides water and methane, ammonia may be the most abundant molecule in the universe with more than two atoms. Measurements of the atmosphere of Jupiter indicate that many of the clouds that we see are composed of frozen ammonia. Jupiter would be a good candidate for *in situ* propellant recovery if one could locate puddles, lakes, or glaciers of ammonia on other celestial bodies or scoop up ammonia on a flyby without dipping too deep into the atmosphere.

A major disadvantage of the use of anhydrous ammonia as a rocket propellant is its low density and the fact that it is not hypergolic with most oxidizers. Liquid ammonia was present on every Space Shuttle flight; it was used on the Space Shuttle orbiter as a dump (open-cycle) coolant to cool the fluorocarbon fluid that circulated through the heat exchangers in the crew compartment to provide air-conditioning and keep the computers at a safe operating temperature, in particular during re-entry and aerodynamic heating. The ammonia dump cooling was active only during the re-entry phase when much of the re-entry aerodynamic breaking heat had to be dissipated away from the crew compartment.

Liquid ammonia is pumped through several loops around the International Space Station (ISS) as a coolant and heat transfer fluid in the climate (temperature) control of the inhabited modules and to cool heat-producing computers and experiments. There have been several incidents of ammonia leaking from the ISS. Every once in a while, an ammonia pump has to be replaced. Ammonia leaks are a problem for astronauts performing extra-vehicular activity (EVA) during maintenance when ammonia crystals adhere to their space suits and get dragged into the air lock when they re-enter the ISS.

Liquid ammonia and ammonia mixtures have been considered as alternative automotive fuels [2–4]. When the supply of liquid and gaseous fossil fuels is exhausted a few centuries from now, there may be an economy based on hydrogen and ammonia as transportation fuels, although there is concern about  $\text{NO}_x$  formation during the combustion of ammonia (Section 10.1) [5].

At the same time, ammonia injection into stack gases of fossil fuel-burning stationary power plants is used as a method to **remove**  $\text{NO}_x$  before the stack gases are vented into the atmosphere in populated areas to minimize smog and air pollution. In the De $\text{NO}_x$  process, the gases with a carefully metered amount of ammonia are passed over a catalyst and the only products leaving the stack are nitrogen and water (besides the carbon dioxide, unchanged). Most likely, the first vehicle to be powered with liquid ammonia in an internal combustion engine or an air/ammonia/hydrogen fuel cell will be a farmer's tractor that plows the field and applies ammonia as a fertilizer since it has ammonia on board anyway and the driver is used to handling it. The delivery tanker from the ammonia production plant to the agricultural distribution center might also be powered by liquid ammonia instead of diesel fuel.

A widespread infrastructure for the supply of hydronitrogen fuels exists in the USA. For instance, there are ammonia pipelines such as the Magellan pipeline system which extends 1100 miles from Texas to Minnesota and serves 13 supply points along the route, and the Kaneb Pipeline Partners which extends 2090 miles from seaports on the Gulf of Mexico to North Dakota and Wyoming serving 17 supply points. Unfortunately, there have been several ammonia pipeline ruptures [6] with adverse effects similar to the other ammonia transportation spill events (see Section 7.7.1).

There have been logistics studies assuming that a military base in a hostile area, cut off from all supply routes but with an ample supply of electric power from a mobile nuclear reactor power plant, could use nitrogen from the air and hydrogen from water electrolysis to generate ammonia for use as a fuel for vehicles including internal combustion, fuel cell, and jet engine-driven vehicles [7–9]. Some of this mobile, modular ammonia plant technology, once it is developed for use on Earth, might even be useful for the production of ammonia on extraterrestrial bases, assuming that water and nitrogen will be available as *in situ* resource utilization (ISRU) feedstock locally.

Hydrogen is a clean form of energy but is difficult to store. Liquid ammonia is easy to store and would be an efficient method for storing hydrogen, provided there is sufficient energy available to catalytically dissociate ammonia into dinitrogen and dihydrogen at the point of end use [10]. The hydrogen content in liquid ammonia is 17.6 mass-% compared with only 12.5% in methanol. The volumetric storage density of hydrogen in liquid ammonia at room temperature is  $0.106 \text{ g/cm}^3$  whereas the density of cryogenic hydrogen at its normal boiling point is only  $0.085 \text{ g/cm}^3$ . Per unit volume, liquid ammonia has 1.3 times the heating value of liquid hydrogen. Ammonia could play a major role in a hydrogen economy in the future [11]. Ammonia and/or its hydronitrogen relative hydrazine can be used in fuel cells with oxygen or air as the oxidizer [12].

Ammonia evaporation and condensation is an efficient method for closed-loop heat pipes that can operate on the ground as well as in outer space. The condensed liquid returns to the evaporator by capillary action through a wick. Ammonia heat pipes are now widely used to cool the electronic compartments in large satellites.

Operating at much higher temperatures and much higher pressures than the physical heat pipes currently in use, a **chemical** heat pipe would dissociate ammonia into its elements at the hot end (typically in a nuclear reactor or solar thermal power plant), transport the dissociation products from point A to point B, and allow the gases to recombine over a catalyst at the cold end where the heat released could be used for residential heating or industry.

Standard chemical reference sources such as *Ullman's Encyclopedia of Industrial Chemistry* [13, 14] and the *Kirk-Othmer Encyclopedia of Chemical Technology* [15] contain detailed chapters with most of the information needed for the design of ammonia systems. We don't want to repeat this information, but rather collect and present here all information related to the use of liquid ammonia as a rocket propellant.

## 2 Production of Ammonia

Ammonia can be prepared from the elements nitrogen and hydrogen at high pressure in the presence of a catalyst. The Haber–Bosch process was developed in Germany in 1913 and has had a dramatic impact on the availability of fertilizers and other nitrogen chemicals worldwide. It has allowed high-intensity farming and has multiplied the number of crops that can be harvested on poor soil, thus feeding millions of people that would otherwise starve or depend on other types of nitrogen-rich fertilizers (manure and sewage).

Ammonia is currently produced by the Haber–Bosch process which is very energy- and capital-intensive. In search for more efficient and economical processes and in view of the potential use of ammonia as an energy carrier, a number of new processes are under development. Among these, electrochemical routes have the potential to substantially reduce the energy input (by more than 20%), simplify the reactor design, and reduce the complexity and cost of production facilities when compared to the high-pressure ammonia production route. Several electrochemical routes based on liquid, molten salt, or solid electrolytes are currently under investigation [16].

Prior to the invention of the Haber–Bosch process, the main route to synthetic production of ammonia by atmospheric nitrogen fixation was by means of cyanamide. The USA is the world's largest importer of ammonia, approximately 6.3 million metric tons during 2010 [17, 18]. The upward trend in US prices of natural gas from 2000 to 2006 led to a 17% decline in the national supply of ammonia. US ammonia production declined by more than 4%, while ammonia imports increased 115% in the same time frame and the shares from imports increased from 15 to 42%. The decline in production raised the price for farmers 130% from \$227 per ton in 2000 to \$521 per ton in 2006. Prices in 2011 were above \$800/metric ton. Department of Commerce figures showed a 36% increase in ammonia imports during the month of April 2011 alone.

An increasing amount of ammonia, although still small compared with other uses, is used as a concentrated solution in combating the discharge of polluting nitrogen oxides in the smoke stacks from fossil-fueled power stations.

Ammonia ranks second to sulfuric acid as the chemical with the largest tonnage. It is being increasingly produced in countries which have low-cost sources of natural gas and coal (China and Russia account for ca. 40%). The largest plants produce about 3000 tons a day, and there are plans to build plants that produce 4000–5000 tons a day, which would mean that the total world output could be managed with 100 such units. As of 2011, ammonia production was:

|               |                  |
|---------------|------------------|
| Global        | 140 million tons |
| Europe        | 16 million tons  |
| North America | 15 million tons  |
| USA           | 8 million tons   |

|                 |                   |
|-----------------|-------------------|
| Asia            | 74 million tons   |
| Russia          | 12.5 million tons |
| The Middle East | 13 million tons   |

Eighty-five percent of all ammonia produced is used as fertilizer and 5% is converted to nitric acid, and most of this goes into the production of nitrate fertilizers [19].

### 3 Physical Properties of Ammonia

Because ammonia has been known for a long time and because it is an important intermediate in many chemical processes, its physical properties are well documented. Some physical properties needed for designing the equipment for using ammonia under extreme conditions, such as those encountered in a rocket engine, have been determined specifically for this application.

Although this chapter deals with ammonia  $^{14}\text{NH}_3$  as a rocket propellant, the properties of its isotope analogs (isotopologs)  $\text{ND}_3$  and  $^{15}\text{NH}_3$  are sometimes listed here for comparison, in particular in the section on its spectroscopic properties. There is always some  $\text{NH}_2\text{D}$ ,  $\text{NHD}_2$ , and  $\text{ND}_3$  present in commercial  $^{14}\text{NH}_3$  due to the natural isotope distribution in nitrogen and hydrogen from which this chemical is made, and this small percentage may affect some of its physical properties. Although  $\text{ND}_3$  will never be used as a rocket propellant, some of its properties are nevertheless included here for reference; it may be of interest as a fuel for chemical lasers. Chemical D-F lasers depend on a source of deuterium. The other isotopologue,  $^{15}\text{NH}_3$ , is also present in small amounts in natural ammonia. It would be useful for kinetic reaction studies with isotope-labeled ammonia and hydrazine, for instance, to examine the effect of ammonia dissociation on the rocket performance of hydrazine monopropellant and compare the ammonia dissociation activity of different catalysts.

There are numerous physical property compilations for ammonia and other refrigerants assembled by the refrigeration industry. If physical or thermodynamic property data for ammonia cannot be found in the book at hand, it may be possible to find them in refrigeration system design handbooks. Oddly enough, ammonia and some of the other non-halocarbon refrigerants have been assigned numbers similar to the halocarbon refrigerants. Ammonia is sometimes listed as Refrigerant 717.

For quick and approximate calculations, the physical properties of ammonia can be read from a nomograph [20]. A frequently used summary of physical properties of ammonia appears in *Chemical Engineering* [21]. A chapter in *USAF Propellant Handbooks, Hydrazine Fuels*, AFRPL-TR-69-149, [22] gives a complete summary of the physical properties of ammonia and several images in this chapter have been derived from this source.

### 3.1 Freezing Point, Melting Point, Triple Point, and Phase Diagrams of Ammonia

Freezing point data for ammonia are summarized in Table 1.

**Table 1:** Freezing point of ammonia.

|                | K                    | °C                    | References |
|----------------|----------------------|-----------------------|------------|
| Freezing point | 195.41               | −77.74                | [23]       |
|                | 194.95               | −78.2                 | [24]       |
| Triple point   | 195.41 at 6.076 kPa  | −77.74 at 45.58 mm Hg | [23]       |
|                | 195.5 at 0.06060 bar | −77.6                 | [24]       |
|                | 195.4 at 6.0182 kPa  | −77.5                 | [25]       |

For a rocket propellant, ammonia will be kept in its liquid form, but frozen ammonia shows unusual multi-phase behavior which may affect other physical properties. It is highly unlikely that ammonia in a rocket engine will ever be exposed to conditions that cause it to undergo phase transitions like those described here, but ammonia that exists in the atmospheres, solid cores, and icy moons of the outer planets in our solar system may be under very high pressures; this totally changes its phase behavior from what we are used to at Earth's atmospheric pressure, also in combination with ice or in the presence of hydrogen which would complicate the phase diagram even further. We also need to know if ammonia under conditions of high pressure would convert to other previously unknown hydronitrogens like  $N_2H_6$  or  $NH_5$  which might be useful as rocket fuels.

The different phases of solid ammonia are usually represented by Roman numerals. They can be identified by X-ray diffraction (XRD), ultrasound attenuation, and Raman spectra. The molar volumes of ammonia solids I and II were measured from 0.5 to 14.0 kbar and from 185 to 320 K [26–28]. Over regions that extend 3 kbar and 20 K into the solid phases, variations in compressibility and thermal expansion could be described by power laws with exponents similar to those usually associated with critical transitions. It has been suggested that the breaking of hydrogen bonds may account for the extreme softening of solid ammonia.

The phase line equations were calculated using the mean field theory for the liquid–solid I/solid II phases in ammonia close to the melting point [29]. The calculated phase diagram agreed very well with the experimentally obtained  $P$ – $T$  phase diagram from the literature. Similar calculations were made for phases I, II, and III of solid ammonia [30].

A phase diagram of solid ammonia is shown in Figure 1. Above 4 GPa, three different phases may be stabilized depending on the temperature. In increasing order of temperature, these are the ordered, orthorhombic phase IV, the plastic (orientationally disordered) cubic phase III, and the fluid. The IV–III and III–fluid transition

**Figure 1:** Phase diagram of solid ammonia. (Reproduced and modified from [31], with permission of ©2008 AIP Publishing.)

lines have been determined up to 373 K. Experimental measurements of the phase diagram of NH<sub>3</sub> in the ranges 1–20 GPa and 300–900 K have been made and the III–IV transition line has been determined up to 20 GPa and 500 K in order to detect the influence of the isostructural phase transition [31]. The melting curve has been determined up to 9 GPa and 905 K. No evidence for the superionic phase has been observed in this  $P$ – $T$  range. No discontinuity is observed at the expected location for the III–IV–V triple point.

Temperature and pressure dependencies of the molar volume were studied along the transition curve between the solid I and solid II phases near the melting point in solid ammonia [32]. The molar volumes were calculated in the temperature range from 217 to 224 K and in the pressure range from 3 to 8 kbar with respect to the triple point ( $T_t = 217.34$  K and  $P_t = 3.070$  kbar), where the melting curves of solid I and solid II coincided with the transition curve in ammonia.

Raman spectroscopic and XRD measurements of ammonia in laser-heated diamond anvil cells at pressures of up to 60 GPa and temperatures of up to 2500 K revealed that the melting line exhibited a maximum near 37 GPa and intermolecular proton fluctuations substantially increased in the fluid with pressure [33]. It was found

that  $\text{NH}_3$  was chemically unstable at high pressures, partially dissociating into  $\text{N}_2$  and  $\text{H}_2$ . *Ab initio* calculations showed that this process is thermodynamically driven. The chemical reactivity dramatically increased at high temperatures (in the fluid phase at  $T > 1700\text{ K}$ ) almost independently of pressure. Quenched from these high-temperature conditions,  $\text{NH}_3$  exhibited structural differences from known solid phases.

It appears that solid molecular ammonia becomes unstable at room temperature and a high pressure, and transforms into an ionic crystalline form [34]. This material has been characterized in both  $\text{NH}_3$  and  $\text{ND}_3$  ammonia samples of up to about 180 and 200 GPa, respectively, by IR absorption, Raman spectroscopy, and XRD. The presence of a new, strong IR absorption band centered at  $2500\text{ cm}^{-1}$  in  $\text{NH}_3$  ( $1900\text{ cm}^{-1}$  in  $\text{ND}_3$ ) signals the start of the ionization of ammonia molecules into  $\text{NH}_2^-$  and  $\text{NH}_4^+$  ions, in line with previous theoretical predictions. There are two coexisting crystalline ionic forms, which *ab initio* calculations predict to be the most stable at the relevant pressures. The ionic crystalline form of ammonia is stable at low temperatures, which contrasts with the high-pressure behavior of water in which no equivalent crystalline ionic phase has been found.

### 3.2 Boiling Point of Ammonia

A collection of data for the boiling point of ammonia is presented in Table 2

**Table 2:** Boiling point of ammonia.

|                             | K       | °C     | References |
|-----------------------------|---------|--------|------------|
| Boiling point               | 239.73  | −33.42 | [35]       |
| Boiling point               | 239.823 | −33.3  | [24]       |
| Boiling point               | 239.82  | −33.3  | [24]       |
| Boiling point $\text{NH}_3$ | 239.79  | −33.36 | [25]       |
| Boiling point $\text{ND}_3$ | 242.20  | −30.95 | [25]       |

### 3.3 Density and Molar Volume of Ammonia

Data for the density of solid and liquid ammonia are summarized in Table 3.

The density data in Figure 2 for the low temperature range from the freezing point to 273 K can be represented by the equation

$$\rho = 0.88824 - 4.7742 \times 10^{-4} T - 1.5977 \times 10^{-6} T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin.

**Table 3:** Density of ammonia.

| Physical state | Temperature |      | Density, g/cm <sup>3</sup> |
|----------------|-------------|------|----------------------------|
|                | K           | °C   |                            |
| solid          | 88          | −185 | 0.836                      |
| solid          | 194         | −79  | 0.817                      |
| liquid         | 203         | −70  | 0.7253                     |
| liquid         | 223         | −50  | 0.7020                     |
| liquid         | 243         | −30  | 0.6777                     |
| liquid         | 263         | −10  | 0.6520                     |
| liquid         | 273         | ±0   | 0.6386                     |
| liquid         | 293         | +20  | 0.6103                     |
| liquid         | 298         | +25  | 0.6029                     |
| liquid         | 323         | +50  | 0.5629                     |

Data source: [36]

**Figure 2:** Density of liquid ammonia, low temperature range. (Reproduced and modified from [22].)

The density data in Figure 3 for the high temperature range from 273 to 373 K can be represented by the equation

$$\rho = 0.54529 + 1.89323 \times 10^{-3}T - 5.69427 \times 10^{-6}T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin.

Measurements of the density of liquid ammonia at elevated temperatures and pressures in the compressed liquid phase were carried out with a metal-bellows variable volumometer along 10 isotherms between 310 and 400 K at pressures from the vapor pressure to 17 MPa [37]. The results covered the high-density region from 343 to 601  $\text{kg/m}^3$  summarized in Table 4, and were used to calculate isothermal compressibility and the coefficient of thermal expansion.

Figure 4, which is essentially a combination of Figures 2 and 3 and covers a wider temperature range from 200 to 400 K, illustrates the steep dropoff of density as the liquid approaches the critical point.

Figure 5 gives a density phase diagram with the phase boundaries for ammonia.

The coefficient of thermal expansion of liquid ammonia at atmospheric pressure increases with increasing temperature (Table 5).

The orthobaric density of liquid  $\text{NH}_3$  has been measured from 200 to 287 K, and for liquid  $\text{ND}_3$  from 205 to 273 K [40]. The molar volume of liquid  $\text{NH}_3$  exceeds that of  $\text{ND}_3$  by between 0.8 and 0.9%. The molar volume of the two liquid ammonias can be expressed by the equation

$$V_m = V_{m \text{ ref}} + A(T - T_{\text{ref}}) + B(T - T_{\text{ref}})^2 + C(T - T_{\text{ref}})^3$$

where  $V_m$  is the molar volume in  $\text{cm}^3/\text{mol}$ ,  $V_{m \text{ ref}}$  is the reference molar volume at the triple point in  $\text{cm}^3/\text{mol}$ ,  $T$  is the temperature in kelvin,  $T_{\text{ref}}$  is the triple-point temperature, and A, B, and C are constants listed in Table 6 for both  $\text{NH}_3$  and  $\text{ND}_3$ .

Based on density measurements at pressures from 2 to 17 MPa at four different temperatures (317–398 K), the isothermal compressibility and the cubic expansion coefficient of liquid ammonia were calculated and are displayed in Figure 6a,b [37]. The Tillner-Roth et al. equation of state (EOS) agreed well with the Kasahara et al. results for the cubic expansion coefficient as shown in Figure 6b. The solid lines represent isotherms calculated using the EOS of Tillner-Roth et al. The dashed lines represent isotherms calculated using the EOS of Haar and Gallagher.

A very elegant method to represent the  $\rho VT$  phase diagram of ammonia in a 3-D graph is shown in Figure 7 [41]. To accommodate the full range of data, logarithmic scales were used for pressure and molar volume. Horizontal lines (constant  $\rho T$ ) are tie lines connecting phases (of differing volume) in mechanical and thermal equilibrium across the phase gaps. The label  $T_b$  is attached to the boiling point (100 kPa) tie line. The end dot of the liquid–vapor line in the  $\rho T$  projection represents its termination at the critical point. Volumes in the diagram (actually “space curves,” corresponding to areas in the projections) are labeled solid, liquid, vapor, and (above the critical point) gas. I, II, and III refer to the respective solid phases that can equilibrate with liquid

**Figure 4:** Density of liquid ammonia in the proximity of the critical point. (Reproduced and modified from [38].)

ammonia. Interactive virtual 3-D versions of these phase diagrams, programmed in Jmol, an open-source Java viewer, are also available.

The space curves depicted in Figure 7 are

- A. Solid sublimation, in equilibrium with vapor (estimated)
- B. Vapor condensation, in equilibrium with solid (estimated)
- C. Liquid saturation, in equilibrium with vapor
- D. Vapor saturation, in equilibrium with liquid
- E. Solid–liquid melt equilibria, for solid phases I–III. The two separate curves, for solid and liquid in equilibrium, nearly overlay one another on the scale of the diagram.

Data for ammonia are incomplete in that little information exists below the triple-point temperature ( $195.4\text{ K} = -77.75^\circ\text{C}$ ), and the lines had to be extrapolated. The  $\rho T$  properties of the high-pressure solid phases, I through V, and their relation to the liquid phase were already represented in Figure 1. The II–III–fluid triple point has not yet been determined because no corresponding discontinuity has been observed on the melting curve. Both phases II and III are plastic with large orientational disorder.

Acoustic velocity, refractive index, adiabatic bulk modulus and the EOS of liquid ammonia were determined at temperatures up to 410 K and at pressures up to the solidification point [42]. Sound velocity and refractive index increased smoothly with increasing pressure along isotherms but decreased slightly with the temperature increase. The bulk modulus increased linearly with pressure and its slope  $dB/dP$  decreased slightly with increasing temperature, from 6.67 at 297 K to 5.94 at 410 K.

Density measurements of the compressed-liquid phase for ammonia along four isotherms between 310 and 360 K at pressures from the vapor pressure up to 200 MPa and high densities from 492 to 693 g/cm<sup>3</sup> and vapor pressures at temperatures from 310 to 400 K created conditions of ammonia that would be rarely encountered in a rocket engine, but may exist in the core of icy planets and their moons [43]. The isothermal compressibility and the isobaric expansivity were derived and illustrated on the basis of those measurements.

Density, pressure–volume–temperature (PVT), and  $\rho VT$  data of ammonia, as shown in Figure 8, were also shown in log–log and rectilinear coordinates [44]. Additional data are available from other sources, but require critical examination [45–48].

### 3.4 Compressibility and Velocity of Sound of Ammonia

#### 3.4.1 Compressibility of Liquid Ammonia

Data for the compressibility of solid and liquid ammonia are listed in Table 7.

Figure 9 shows isothermal compressibility data calculated from sonic velocity data measured by Bowen and Thompson [49] and Blagoi et al. [50]. The temperature dependence of the adiabatic compressibility  $\beta$  of liquid ammonia can be expressed by the following equation:

$$\beta = -1.0098 \times 10^{-4} + 1.68095 \times 10^{-6} T - 8.0004 \times 10^{-9} T^2 + 1.5051 \times 10^{-11} T^3$$

where  $\beta$  is the adiabatic compressibility in atm<sup>-1</sup> and  $T$  is the temperature in kelvin.

**Figure 8:** PVT data of ammonia. (Reprinted and adapted from [44], with permission from ©1960 American Chemical Society; permission conveyed through RightsLink.)

**Table 7:** Isothermal compressibility  $\beta$  of solid and liquid ammonia.

| Temperature |       | Compressibility $\beta$ |                        |
|-------------|-------|-------------------------|------------------------|
| K           | °C    | 1/Pa                    | 1/atm                  |
| 222.0       | −51.1 | $6.395 \times 10^{-10}$ | $0.648 \times 10^{-4}$ |
| 249.8       | −23.3 | $8.221 \times 10^{-10}$ | $0.833 \times 10^{-4}$ |
| 273.1       | ± 0   | $1.072 \times 10^{-9}$  | $1.086 \times 10^{-4}$ |

Data source: [39]

**Figure 9:** Adiabatic compressibility of liquid ammonia. (Reproduced and modified from [22].)

### 3.4.2 Velocity of Sound in Liquid Ammonia

The temperature dependence of sonic velocity in liquid ammonia can be expressed by the following equation:

$$c = 3202.49 - 6.1366T$$

where  $c$  is the velocity of sound in m/s and  $T$  is the temperature in kelvin (Figure 10).

Velocities of sound in fluid ammonia at high pressures were measured by Impulsive Stimulated Scattering, up to a pressure of 3.8 GPa and along isotherms of 297, 476, and 680 K [51]. For either liquids or highly compressed gases, plots of velocity of sound against density commonly yield straight lines. To the extent that the EOS of Tillner-Roth gives an adequate account of densities, this relation also holds true for ammonia, as shown in Figure 11. See also [28].

**Figure 10:** Sonic velocity in liquid ammonia at saturation pressure. (Reproduced and modified from [22].)

### 3.5 Vapor Pressure and Vapor Phase Composition of Ammonia

The vapor pressure of liquid ammonia can be calculated from the Antoine equation. The parameters A through C are available for two different temperature ranges and overlap (Table 8).

$$\log (P)_{10} = A - \left( \frac{B}{T + C} \right)$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

Measurements of the vapor pressure of ammonia in the temperature range 195.4–343 K, over which 150 data points were taken in the first of two experiments including 11 determinations for the normal boiling point, gave a historical, frequently quoted set of data [52] (Table 9). The data were taken at near uniform intervals except near the values of temperature associated with important fixed points, for which they were taken over very small intervals.

Vapor pressure measurements from 303.15 K to near the critical temperature were in excellent agreement at lower temperature with those of Cragoe, Meyers, and Taylor

**Figure 11:** Velocity of sound in liquid ammonia at high pressures. (Reprinted and adapted from [51], with permission from ©2008 American Chemical Society; permission conveyed through RightsLink.)

1920 within 0.03% at 303.15 K. However, the difference increased slightly with increasing values of temperature to just under 0.1% at 343.15 K, with an average deviation in this range of about 0.05% [53]. The agreement was within their reported uncertainty. Above 343.15 K, the data agreed with those of Keyes and Brownlee [54] to within 0.1% up to 383.15 K. Differences increased to about 0.2% at 393.15 K and then uniformly to 0.8% at 405.15 K, the highest value of temperature reported, with the values of Beattie and Lawrence being consistently higher throughout. Older measurements by Keyes and Brownlee [54] showed a considerable scatter and, at temperatures below 343 K, large deviations from the very accurate results obtained by Cragoe, Meyers, and Taylor 1920 [42].

**Table 8:** Parameters for Antoine vapor pressure equation for ammonia.

| Temperature range, K | A       | B        | C       |
|----------------------|---------|----------|---------|
| 164.0–239.6          | 3.18757 | 506.713  | –80.78  |
| 239.6–371.5          | 4.86886 | 1113.928 | –10.409 |

Data source: [24]

**Table 9:** Vapor pressure of solid and liquid ammonia.

| Temperature |        | Vapor pressure |        |
|-------------|--------|----------------|--------|
| K           | °C     | kPa            | mm Hg  |

Data source: [52]

Overstreet and Giauque [23] measured the vapor pressure of ammonia from the triple point to 241.6 K. Values of temperature were measured with a special gold resistance-thermometer-heater, but the primary standard was a thermocouple, which was calibrated with a hydrogen gas thermometer and compared from time to time with the gas thermometer.

The vapor pressure of liquid ammonia has been curve-fitted and can be calculated from the following polynomial equation:

$$\log p_v = 30.256818 - 1914.9569/T - 8.4598324 \log T + 2.3930 \times 10^{-3} T + 2.955214 \times 10^{-3} T^2$$

**Figure 12:** Vapor pressure of liquid ammonia. (Reproduced and modified from [22].)

where  $p_v$  is the vapor pressure in mm Hg, and  $T$  is the temperature in kelvin. The temperature dependence of the vapor pressure of liquid ammonia can be expressed by the equation

$$\log p_v = 8.42347 - 1565.85/T - 0.01036T + 1.0269 \times 10^{-5}T^2$$

where  $p_v$  is the vapor pressure in atm, and  $T$  is the temperature in kelvin (Figure 12).

The temperature dependence of the vapor pressure of solid ammonia can be expressed by the equation

$$\log p_v = 1.00094 - 1631.54/T$$

where  $p_v$  is the vapor pressure in mm Hg, and  $T$  is the temperature in kelvin (Figure 13).

The differences in the vapor pressures of ammonia and trideuteroammonia are sufficiently large that one might consider using fractionated distillation of ammonia (instead of fractionated distillation of water) for isotope separation and deuterium production [55]. The differences in the vapor pressures of solid natural ammonia and

**Figure 13:** Vapor pressure of solid ammonia. (Reproduced and modified from [22].)

of isotopologue solid trideuteroammonia containing 98% deuterium were measured and found to be given by

$$\log\left(\frac{P_{\text{NH}_3}}{P_{\text{ND}_3}}\right) = (49.69/T) - 0.1305.$$

The ratio of the vapor pressures of the liquid ammonias were found to follow the equation

$$\log\left(\frac{P_{\text{NH}_3}}{P_{\text{ND}_3}}\right) = (46.25/T) - 0.14003.$$

These two equations agree at the triple point. The difference in the heats of sublimation was calculated to be 950 J (227 cal), while the difference in the heats of vaporization is 887 J (212 cal), the values for the trideuteroammonia being higher than those for ammonia. The triple-point pressures were found to be 45.57 mm Hg for ammonia and 48.22 mm Hg for the trideuteroammonia. This corresponded to triple-point tempera-

tures of 195.68 and 198.79 K, respectively. The boiling point of the  $^{14}\text{N}$  trideuteroammonia was found to be 2.37 K higher than that of the natural ammonia. The ratio of the vapor pressures and the difference in the heats of vaporization of the two pure isotopologues,  $^{14}\text{NH}_3$  and  $^{15}\text{NH}_3$ , were found to be

$$\log\left(\frac{P_{14}}{P_{15}}\right) = (0.7230/T) - 0.005822$$

and

$$\Delta H_{\text{vap } 15} - \Delta H_{\text{vap } 14} = 13.93 \text{ J } (3.33 \text{ cal}).$$

The triple point of the pure  $^{15}\text{NH}_3$  was found to be 0.058 K higher than that of  $^{14}\text{NH}_3$  and the boiling point was 0.052 K higher.

A simple extended corresponding-states principle that can be applied to highly non-spherical substances allows the interpolation and extrapolation of vapor pressures for ammonia and trideuteroammonia and similar polar fluids from the triple point to critical point and can be used to extrapolate the measurements beyond their ranges of available experimental data [25]. To represent experimental data over the entire range, i.e. from the triple point to the critical temperature, the vapor pressure curve was based upon an equation with known physical behavior that has only three substance-dependent parameters

$$\ln p_r = (a_0 + a_1 \tau^{n_1} + a_2 \tau^{n_2}) \ln T_r$$

where  $\tau = 1 - T_r$ , the reduced temperature  $T_r = T/T_c$  with  $T_c$  being the critical temperature, and  $p_r = p/p_c$  with  $p_c$  being the critical pressure. The value of  $n_1$  is 1.89 and the value of  $n_2$  is  $3n_1$  or 5.67. The parameters  $a_0$  and  $a_1$  and  $a_2$  are substance-dependent parameters listed in Table 24 in one of the next chapters on critical point data. The vapor pressures were described accurately by this equation within their scatter in the entire temperature range. Comparisons with the available data showed that the extended corresponding-states principle is capable of calculating the vapor pressure values with accuracies of 0.05–0.1%. The substance-dependent characteristic parameters, such as critical temperature, critical density, critical pressure, acentric factor, and aspherical factor were derived for  $\text{NH}_3$  and  $\text{ND}_3$ . The values of the pressures, along with their first and second derivatives as a function of temperature over the entire region from the triple point to the critical point were tabulated. Vapor pressure data for  $\text{NH}_3$  from 13 different sources in the literature and similar data for  $\text{ND}_3$  from 9 different sources were gathered, critically reviewed, and compared to numbers derived from the corresponding-states principle equation by putting them on a deviation plot with  $T_r$  as the independent variable.

The vapor pressure of liquid ammonia was measured with high accuracy and 16 values were obtained for temperatures between 328 K and the critical temperature ( $T_c$ ) 405.5 K [56]. The results, together with the very accurate measurements reported by Cragoe, Meyers, and Taylor 1920 [52] for temperatures below 343 K, formed the ba-

sis of a new vapor pressure equation. The vapor pressure expressed as the reduced pressure (vapor pressure divided by the critical pressure) can be calculated by the following equation:

$$\ln\left(\frac{p}{p_c}\right) = F(\tau) = \tau^{-1} \{a_1(1-\tau) + a_2(1-\tau)^{1.5} + a_3(1-\tau)^{2.5} + a_4(1-\tau)^5\}$$

$$= F(\tau) = \tau^{-1} [-7.28322(1-\tau) + 1.57160(1-\tau)^{1.5} - 1.85672(1-\tau)^{2.5} - 2.39312(1-\tau)^5]$$

where  $\tau = T/T_c$ ,  $p_c$  = critical pressure = 11.353 MPa, and  $T_c$  = critical temperature = 405.50 K. This equation, containing four terms only, correlated the measured vapor pressures within the limits of experimental accuracy. These data in their region of overlap were in excellent accord with the results of Cragoe, Meyers, and Taylor [52] to within the scatter of those data. They tended to be somewhat lower than the data of Beattie and Lawrence [53]. Near the critical point, the difference was about 0.1%. The uncertainty of the measured temperature was reported to be 0.008 K. The overall accuracy of these data was 0.05%. The differences between this equation and Haar and Gallagher's [57] equation were minor. Below 340 K, both equations correlated the data with the same accuracy. Larger deviations appeared at higher temperatures, where Baehr, Garnjost, and Pollak's equation closely followed the newer measurements which were not available to Haar and Gallagher.

Values of the vapor pressure of ammonia from 293.5 to 392.6 K obtained from triplicate static measurements in a constant-volume apparatus and summarized in Table 10 had a reported accuracy of the measured temperature and pressure of 0.01 K and 0.005%, respectively [47]. Four liquid-phase isochores were measured from 223 to 338 K (−50 to +65 °C), with pressures ranging from saturation pressure to 370 bar. The critical temperature was determined as  $T_c = 405.38 \text{ K} = 132.23 \text{ °C}$  by the visual observation of the disappearance of the meniscus. The deviations between the Zander and Thomas [47] experimental vapor pressures and those calculated according to the equation of Baehr [56] were within the range of experimental precision.

The difference of the vapor pressures of  $\text{NH}_3$  and  $\text{ND}_3$  has been measured as being from 200 to 266 K, and the vapor pressure of  $\text{NH}_3$  from the triple-point temperature up to 234 K [40]. Liquid  $\text{NH}_3$  has a higher vapor pressure than  $\text{ND}_3$ , the difference being relatively large for a pair of isotopic compounds. At 200 K, the ratio of the vapor pressure of  $\text{NH}_3$  to that of  $\text{ND}_3$  was about 1.2. The available vapor pressure data for  $\text{NH}_3$  have been fitted to a Wagner equation. By combining vapor pressures derived from this equation with the differential measurements, values for the vapor pressure of  $\text{ND}_3$  as a function of temperature have been obtained. These values have likewise been fitted to a Wagner equation:

$$\ln\left(\frac{p}{p_c}\right) = (A_0\tau + A_1\tau^{1.5} + A_2\tau^3 + A_3\tau^6)/T_R$$

where  $T_R = T/T_c$ ,  $\tau = (1 - T_R)$ , and  $p_c$  and  $T_c$  are the critical pressure and critical temperature ( $T_c = 405.5 \text{ K}$ ). The triple-point temperature chosen was 195.48 K and

**Table 10:** Vapor pressure of ammonia at temperatures above room temperature.

| Temperature |                    | Vapor pressure    |      |      |
|-------------|--------------------|-------------------|------|------|
| K           | °C                 | bar               | MPa  | psia |
| 293.56      | 20.41 <sup>a</sup> | 8.69 <sup>a</sup> | 0.87 | 126  |
| 303.33      | 30.18              | 11.73             | 1.17 | 170  |
| 313.37      | 40.22              | 15.64             | 1.56 | 227  |
| 323.33      | 50.18              | 20.43             | 2.04 | 296  |
| 333.24      | 60.09              | 26.20             | 2.62 | 380  |
| 343.16      | 70.01              | 33.11             | 3.31 | 480  |
| 353.10      | 79.95              | 41.34             | 4.13 | 600  |
| 362.98      | 89.83              | 50.96             | 5.10 | 739  |
| 372.88      | 99.73              | 62.16             | 6.22 | 901  |
| 382.73      | 109.58             | 75.10             | 7.51 | 1089 |
| 392.64      | 119.49             | 90.16             | 9.02 | 1308 |

Data source: [47]

<sup>a</sup> Note: Data from triplicate measurements in original publication were rounded off

the triple-point pressure was  $(6.079 \pm 0.003)$  kPa. For  $\text{NH}_3$ , the coefficients were  $\ln(p_c) = 9.33717$ ;  $A_0 = -7.20816$ ;  $A_1 = 1.23966$ ;  $A_2 = -2.3783$ , and  $A_3 = -1.528$ . The standard deviation of  $\ln p$  is  $+1.6 \times 10^{-3}$ , while  $p_c$  estimated in this way is  $(11352 \pm 3)$  kPa, virtually the same as the value of 11355 kPa proposed by Baehr et al. For  $\text{ND}_3$ , taking  $T_c \text{ND}_3 = 405.3$  K, the parameters obtained for the Wagner equation were:  $A_0 = -7.05354$ ;  $A_1 = 0.36799$ ;  $A_2 = -0.6903$ ;  $A_3 = -7.006$ , and  $\ln p_c = 9.34824$  (kPa). This corresponds to  $p_c = 11.48$  MPa, which is just an estimate.

The h-d vapor pressure isotope effect in liquid ammonia has been measured at 62 temperatures between 228 and 260 K [58]. The vapor pressures, corrected to 100% nuclidic purity, have been fitted to the equation:

$$T \ln r = A + \frac{B}{T} + CT,$$

where  $r$  is the vapor pressure ratio  $p(\text{NH}_3)/p(\text{ND}_3)$ . The least-squares fit yielded the parameters:

$$A = -(8.22508 \pm 0.03706) \text{ K}, \quad B = (12.3382 \pm 1.1833) \times 10^3 \text{ K}^2, \quad \text{and} \\ C = -(0.05544 \pm 0.02043).$$

Comparisons with the results of other authors were made in order to clarify some discrepancies found in the literature. The values were in accord with the previous results of King et al. and an extrapolation of the fitted equation down to the triple-point temperature gave good agreement with published results. The fitted equation was used in conjunction with the Clapeyron equation to calculate the difference in the molar

enthalpies of vaporization between  $\text{NH}_3$  and  $\text{ND}_3$ . At  $T = 230\text{ K}$ , the difference was  $-846\text{ J/mol}$ , decreasing to  $-747\text{ J/mol}$  at  $260\text{ K}$ .

Fourteen vapor pressure, eight near-saturation vapor ( $P, \rho, T$ ), and 28 near-saturation liquid ( $P, \rho, T$ ) data points of liquid ammonia were measured over a temperature range from  $279$  to  $392\text{ K}$  and are summarized in Table 11, see [59]. In addition to data for pure ammonia, liquid-phase isothermal ( $P, \rho, T$ ) and bubble-point-pressure measurements for two standard mixtures of  $\text{NH}_3 + \text{H}_2\text{O}$  ( $x_{\text{NH}_3} = 0.8360$  and  $0.9057$  mol fraction) (not suitable as rocket propellants) were taken over a temperature range from  $280$  to  $379\text{ K}$  and at pressures of up to  $7.7\text{ MPa}$ . These data were compared to literature data and correlations, and agreed within  $\pm 3\%$  for bubble-point pressures,  $\pm 0.005\text{ g/cm}^3$  for liquid densities, and  $\pm 0.0011\text{ g/cm}^3$  for vapor densities.

**Table 11:** Near-saturation liquid ( $P, \rho, T$ ) vapor pressure and density measurements for  $\text{NH}_3$ .

Data source: [59]

Measurements of ( $P$ ,  $\rho$ ,  $T$ ) for  $\text{NH}_3$  at elevated temperatures and pressures in the compressed liquid phase were carried out with a metal-bellows variable volumometer along 10 isotherms between 310 and 400 K at pressures from the vapor pressure to 17 MPa at intervals of 10 K [37]. The experimental uncertainties in temperature  $T$ , pressure  $P$ , and density  $\rho$  were estimated to be less than  $\pm 4$  mK,  $\pm 1.0 \times 10^{-3} P$ , and  $\pm 1.0 \times 10^{-3} \rho$ , respectively. The vapor pressure measurements of Baehr, Garnjost, and Pollak [56] were lower than the Kasahara et al. [37] results, but the differences were within the uncertainty of the Kasahara et al. measurements.

Vapor pressures of ammonia were measured for three different temperatures as part of an effort to obtain more accurate critical point data and are summarized in Table 12.

**Table 12:** Vapor pressure of ammonia.

| Temperature |     | Vapor pressure |       |
|-------------|-----|----------------|-------|
| K           | °C  | MPa            | atm   |
| 310         | 37  | 1.423          | 14.04 |
| 350         | 77  | 3.867          | 38.16 |
| 400         | 127 | 10.302         | 101.7 |

Data source: [60]

### 3.6 Viscosity of Ammonia

One must differentiate between *dynamic* viscosity and *kinematic* viscosity. The SI physical unit of dynamic viscosity is the Pascal-second (Pa s), equivalent to  $(\text{Ns})/\text{m}^2$ , or  $\text{kg m}^{-1} \text{s}^{-1}$ . The cgs physical unit for dynamic viscosity is the *poise*, abbreviated as P or Ps.

$$1 \text{ Ps} = 0.1 \text{ Pa} \cdot \text{s}$$

$$1 \text{ cPs} = 1 \text{ mPa} \cdot \text{s} = 0.001 \text{ Pa} \cdot \text{s}.$$

The SI unit of kinematic viscosity is  $\text{m}^2/\text{s}$ . The cgs physical unit for kinematic viscosity is the *stokes*, abbreviated as St. It is sometimes expressed in terms of centistokes (cSt).

$$1 \text{ St} = 1 \frac{\text{cm}^2}{\text{s}} = 10^{-4} \frac{\text{m}^2}{\text{s}}$$

$$1 \text{ cSt} = 1 \frac{\text{mm}^2}{\text{s}} = 10^{-6} \frac{\text{m}^2}{\text{s}}.$$

3.6.1 Viscosity of Liquid Ammonia

Data for the viscosity of liquid ammonia are listed in Table 13 and illustrated in Figure 14.

**Table 13:** Viscosity and density of liquid ammonia under pressure.

| Temperature |    | Density           | Viscosity |        |
|-------------|----|-------------------|-----------|--------|
| K           | °C | g/cm <sup>3</sup> | mPa s     | cPs    |
| 278         | 5  | 0.63197           | 0.1618    | 0.1618 |
| 288         | 15 | 0.61821           | 0.1457    | 0.1457 |
| 298         | 25 | 0.60427           | 0.1350    | 0.1350 |

Data source: [61]

**Figure 14:** Viscosity of saturated liquid ammonia. (Reproduced and modified from [22].)

When plotting viscosity data for liquid ammonia gathered from ten different sources, there was more scatter in the data than for most other physical properties. Two of the data sets (shown in solid symbols in Figure 14) had to be eliminated before calculat-

ing smoothed interpolated data represented by a polynomial equation. Carmichael, Reamer, and Sage [62] reviewed the available data and compared them to measurements they made in a rotating cylinder viscometer. All of these measurements were made in the temperature range 370–480 K and pressures below 345 bar. The solid triangles represent data from Carmichael and Sage [63]. The temperature dependence of the viscosity of liquid ammonia can be calculated by the following curve-fitted equation:

$$\log \mu = 5.7757 - 0.05837T + 1.7980 \times 10^{-4}T^2 - 1.9689 \times 10^{-7}T^3$$

where  $\mu$  is the viscosity in centipoise and  $T$  is the temperature in kelvin.

Viscosity data for ammonia and methylamine and several associated liquids have been obtained in the temperature ranges –65 to –35 °C and –65 to –10 °C, respectively, using an Ubbelohde viscometer [64] (Table 14). The results were compared with existing data, and all the data were fitted to the Fulcher (Tammann–Hesse) equation by the method of least squares. The significance of the values of  $T_0$  in this equation for these and other associated liquids was considered and it was attempted to give an interpretation to the significance of  $T_0$ . When comparing the different  $T_0$ , it can be noted that the quantity  $T_0$  (also written as -C by some authors) is largest for those liquids in which very extensive hydrogen bonding is possible.

**Table 14:** Viscosity of liquid ammonia and methylamine at various temperatures.

| Ammonia             |                    | Ammonia             |                    | For comparison: methylamine |                    |

Data source: [64]

The viscosity data in Table 14 can be expressed by a Fulcher-type equation

$$\log \eta = A + B/(T - T_0)$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The constants A, B, and  $T_0$  for ammonia are summarized in Table 15 below in comparison to other associated (hydrogen bonded) liquids.

Viscosity of ammonia measurements on five isotherms in the temperature range 448–598 K and pressures of up to 121 bar were made in a steady-state, capillary-flow viscometer [65]. The measurements were estimated to be accurate to better than 0.4% over the full range.

It was no easy task to bring together viscosity data for liquid and gaseous ammonia from over 40 different sources, spanning a time frame from 1846(!) to 1993 and temperatures from 196 K to beyond the critical point, and arrive at a consensus as to which data are reliable and should be used for a statistical averaging of results [66]. The majority of the primary set of experimental data was obtained from methods using either an oscillating disk or a capillary-flow apparatus. For the liquid phase, there is a paucity of reliable data. Only the later data from Carmichael, Reamer, and Sage [62] and Makhija and Stairs [64] were judged to be sufficiently accurate to be included in the primary set. The viscosity of ammonia in the liquid and gas phases was measured at pressures up to 34.5 MPa (5000 psia) in the temperature interval between 277.6 and 477 K (40 and 400 °F) by Carmichael, Reamer, and Sage [62]. The measurements were obtained with a rotating-cylinder viscometer, and results were presented in tabular and graphical form. Comparison with earlier measurements indicated fair agreement. The viscosity excess appeared to be a single-valued function of the specific weight. The

earlier data of Carmichael and Sage [63] tend towards low values at higher temperatures (343–373 K = 70–100 °C), but this seems to be a real effect due to the increasing specific volume of ammonia under its own vapor pressure at these temperatures. Raw (unsmoothed) viscosity data for liquid ammonia are summarized in Table 16. Deviation plot graphs were used to illustrate the deviation of data reported by individual investigators from the best correlation of Fenghour et al. [66], as a function of temperature. The best correlation for the viscosity of liquid ammonia and gaseous ammonia along the saturation line is summarized in Table 16. The effect of high pressures on the viscosity of liquid ammonia is illustrated in Figure 15.

**Table 16:** Viscosity and density of liquid and gaseous ammonia along the saturation boundary.

### 3.6.2 Viscosity of Gaseous Ammonia

Below 5 bar, the viscosity and thermal conductivity of gaseous ammonia do not show much dependence on pressure (Figure 16).

At higher pressures, the association of polar molecules causes a non-linear behavior of these properties with pressure. Measured viscosity data, a composite from ten different sources, of gaseous ammonia were fitted to an equation based on molecular collision theory containing terms for polarity parameter, dipole moment, collision diameter, and the maximum energy of attraction [67]. This equation would allow us to extrapolate (dashed lines in Figure 17) beyond the range of measured data (solid lines in Figure 17) both in the direction of higher and lower temperatures. The critical temperature used for this graph was 405.5 K.

### 3.6.3 Viscosity of Supercritical Ammonia

Viscosity values at high, supercritical pressures and for the liquid state are difficult to obtain. High pressure viscosity data for ammonia are often scattered with wide error margins. Limited experimental data on ammonia for both viscosity and thermal conductivity necessitated the use of the theory of Enskog for the calculation of these transport properties at elevated pressures [67]. The residual viscosity  $\mu - \mu^*$  can be related directly to the reduced density  $\rho/\rho_c$  of ammonia as shown in Figure 18, where  $\mu^*$  is the thermal conductivity at moderate pressures and  $\rho/\rho_c$  is the density divided by the critical density. The critical density used for this graph was  $0.235 \text{ g/cm}^3$ .

### 3.7 Surface Tension of Ammonia

Measured data for the surface tension of liquid ammonia are tabulated in Table 17. The surface tension of liquid ammonia from 198 to 229 K (−75 to −44 °C) and of salt solutions in ammonia of sodium chloride and bromide and potassium bromide and iodide at 229 K (−44 °C) were measured by the method of maximum bubble pressure and checked by a few measurements by the capillary rise method [68]. The surface tension of ammonia may be represented by the equation

$$\sigma = 23.41 - 0.3371t - 0.000943t^2$$

**Figure 18:** Residual viscosity as a function of reduced density of ammonia in the dense phase/supercritical region. (Reprinted and adapted from [67], with permission from ©1961 American Chemical Society; permission conveyed through RightsLink.)

**Table 17:** Surface tension of ammonia

| Temperature |       | Surface tension $\sigma$ |        |
|-------------|-------|--------------------------|--------|
| K           | °C    | N/m                      | dyn/cm |
| 217         | −56   | 0.039                    | 39.15  |
| 221.4       | −51.7 | 0.038                    | 38.30  |
| 234         | −39   | 0.036                    | 35.56  |
| 239         | −34   | 0.034                    | 34.39  |
| 240         | −33   | 0.034                    | 34.06  |
| 284.2       | 11.1  | 0.023                    | 23.38  |
| 307.2       | 34.05 | 0.018                    | 18.00  |
| 332.13      | 58.98 | 0.013                    | 12.95  |

Data source: [39]

Conversion factors  $1 \text{ dyn} = 10^{-5} \text{ N}$ ;  $1 \text{ dyn/cm} = 10^{-3} \text{ N/m} = 1 \text{ mN/m}$

with a standard error of  $\pm 0.15$  dyn/cm where  $\sigma$  is the surface tension in dyn/cm and  $t$  is the temperature in  $^{\circ}\text{C}$ .

The temperature dependence of the surface tension of liquid ammonia can be calculated by the following curve-fitted equation:

$$\sigma = 89.8093 - 0.23252T$$

where  $\sigma$  is the surface tension in dyn/cm and  $T$  is the temperature in kelvin as shown in Figure 19.

**Figure 19:** Surface tension of liquid ammonia. (Reproduced and modified from [22].)

### 3.8 Thermal Conductivity of Ammonia

The thermal conductivity (also called *thermal conductance*) of ammonia is an important physical property needed in the design of commercial refrigeration machinery and regenerative cooling jackets in rocket engines that operate with liquid ammonia as a fuel. Temperature conditioning circuits on board the ISS are operating with liquid ammonia, and, every once in a while, an ammonia pump has to be replaced. The Space Shuttle orbiter had an ammonia evaporation dump coolant circuit with a heat

exchanger to a fluorocarbon coolant circuit to keep the crew compartment and electronics bays cool during re-entry. All these circuits were designed based on knowing the thermal conductivity and heat transfer characteristics of liquid ammonia. Considering the wide use of ammonia as a heat transfer fluid, it is surprising to discover the wide spread of data reported in the literature on the thermal conductivity of liquid ammonia at sea level pressure, ammonia at the saturation line, and gaseous ammonia. In many instances, the interference caused by convection resulted in high numbers. Some of the discrepancies carry over into this chapter and have not yet been resolved. Because so many different units of measurement are used for thermal conductivity, it is difficult to bring data from different sources to a common denominator for comparison.

### 3.8.1 Thermal Conductivity of Liquid Ammonia

Liquid ammonia as a refrigerant and heat transfer fluid is used in huge quantities in industrial refrigeration installations and even on board the ISS. It is surprising that it is very difficult to obtain consistent quality data for the thermal conductivity of liquid ammonia from the literature. Various investigators contradict each other about the dependence of the thermal conductivity of liquid ammonia on temperature. Some sources predict that the thermal conductivity increases with temperature, while other, more reliable data indicate that the thermal conductivity will decrease with temperature. Some of the older data for the thermal conductivity of liquid ammonia which showed an increase are summarized in Table 18.

**Table 18:** Thermal conductivity of liquid ammonia.

| Temperature |         | Thermal conductivity, $\lambda$ |                                                   |                                                   |
|-------------|---------|---------------------------------|---------------------------------------------------|---------------------------------------------------|
| K           | °C      | $\text{W m}^{-1} \text{K}^{-1}$ | $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$ | $\text{cal cm}^{-1} \text{s}^{-1} \text{°C}^{-1}$ |

Data source: [39]

Figure 15 on page 11 of Noel 1961, which the accompanying text described as representing liquid thermal conductivity data, showed an increase of thermal conductivity with temperature, supposedly based on data from Perry and Kordos (see [69]). Based on the increasing slope, the data used were most likely for gaseous ammonia and not liquid ammonia. This error was unfortunately not detected or corrected when the figure was used without further verification in a 1968 edition of this book on rocket propellants. The mislabeled figure has since been removed from the manuscript

for a revised edition. Figures 24 and 25 also show that the thermal conductivity of gaseous ammonia increases with temperature, similar to what appeared in the Noel 1961 report, Figure 15 [69]. *Perry's Chemical Engineers' Handbook*, 5<sup>th</sup> ed., on pages 3–214, cites a single number for Kardos 1933, 1934 data from 5 to 86 °F as  $0.29 \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1} = 0.00120 \text{ cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1} = 0.501 \text{ W m}^{-1} \text{ K}^{-1}$  for liquid ammonia. Yaws in *Chemical Engineering*, vol. 81, Issue No. 25, page 97, Unit 6, Figure 6–10 shows a decrease in the thermal conductivity of liquid ammonia with temperature. Interpolating from the graph, the thermal conductivity of saturated liquid ammonia at 298 K would be  $11 \times 10^{-4} \text{ cal s}^{-1} \text{ cm}^{-1} \text{ °C}^{-1} = 0.46 \text{ W m}^{-1} \text{ K}^{-1}$ , similar to the Perry/Kardos number.

Sellschopp [70] determined the thermal conductivity of saturated liquid ammonia under pressure between 303 and 373 K (30 and 100 °C) and expressed the data by means of the equation

$$\lambda = 12.889(1 - 0.0042t) \times 10^{-4}$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1}$  and  $t$  is the temperature in °C. This equation gives a thermal conductivity of  $11.5 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ °C}^{-1} = 0.48 \text{ W m}^{-1} \text{ K}^{-1}$  for a temperature of 298 K = 25 °C, similar to the numbers discussed in the previous paragraph.

The unique relationship between the thermal conductivity and density, which was shown to exist for some monatomic and diatomic gases in their liquid and liquid-like fluid states, appears to also hold for ammonia. With the aid of this correlation, a value of  $3.65 \pm 0.06 \times 10^{-4} \text{ cal cm}^{-1} \text{ °C}^{-1} \text{ s}^{-1} = 0.153 \text{ W m}^{-1} \text{ K}^{-1}$  was found for the apparent thermal conductivity at the critical point [71].

The thermal conductivity of liquid and gaseous ammonia was measured in a spherical conductivity cell at pressures of up to 34.5 MPa (5000 psia) in the temperature interval between 278 and 478 K (40 and 400 °F) [72]. The results at atmospheric pressure agreed satisfactorily with earlier measurements. The residual thermal conductivity was a single-valued function of density for both the liquid and gas phases. This investigation did not include the critical region. Figures 20 and 21 show the experimental values of the thermal conductivity of gaseous and liquid ammonia at zero thermal flux as a function of pressure for each of the several temperatures investigated. A linear relationship between the apparent thermal conductivity and the thermal flux was assumed in this range of flux. Obviously, this was not strictly true. The standard error of estimate of these values of thermal conductivity from the smooth data was  $0.00277 \text{ W m}^{-1} \text{ K}^{-1}$  ( $0.0016 \text{ BTU h}^{-1} \text{ ft}^{-1} \text{ °F}^{-1}$ ). The behavior at 411 K (280 °F), which was similar to that encountered with other fluids in the critical region, has been indicated by a dashed curve, since insufficient measurements were obtained to establish the behavior in this region with an accuracy equivalent to that at other states more distant from the critical region. The behavior in the gaseous region at lower pressures is shown in Figure 20.

**Figure 20:** Effect of low pressure on thermal conductivity of liquid and gaseous ammonia. (Reprinted and adapted from [72], with permission from ©1964 American Chemical Society; permission conveyed through RightsLink.)

The thermal conductivity of liquid and supercritical ammonia has been determined as being between 293 and 450 K (20 and 177°C) and at pressures from 0.1 to 50.7 MPa (1 to 500 atm), mapping the vicinity of the critical point ( $p_c = 11.3 \text{ MPa} = 111.5 \text{ atm}$ ,  $t_c = 132.4^\circ\text{C} = 405.5 \text{ K}$ ) along the reduced isotherms, 1.016 and 1.061, using a vertical, co-axial-cylinder apparatus [71, 73]. The measured thermal conductivity at 293 K was  $11.74 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ }^\circ\text{C}^{-1} = 0.49 \text{ W m}^{-1} \text{ K}^{-1}$ , in good agreement with literature data. An anomalous increase of thermal conductivity in the critical point regime has been found, similar to that for carbon dioxide. This anomaly becomes more visible if plotting the thermal conductivity versus the density in Amagat units. In Figure 22,  $k$  as a function of density is shown for three different temperatures. The solid straight line delineates normal behavior at 450 K = 176.9°C. The deviations from

**Figure 21:** Effect of high pressure on thermal conductivity of liquid and gaseous ammonia. (Reprinted and adapted from [72], with permission from ©1964 American Chemical Society; permission conveyed through RightsLink.)

this line,  $\Delta k$ , are shown in the two dashed-line curves below. The  $\Delta k$  deviation curves max out at 250 and 314 Amagat, corresponding to pressures of 125 and 164 atm, respectively.

A tentative explanation of this phenomenon was given, based on the transport of energy by clusters of molecules. Experimental results for the liquid-like fluid state, both below and above the critical temperature, have been correlated by a quadratic equation between density and thermal conductivity. With the aid of this equation, values have been extrapolated for conditions outside those of the experimental range. Many investigators extrapolating thermal property data to higher temperatures have ignored the fact that ammonia begins to decompose at temperatures above 700 K.

The temperature dependence of the thermal conductivity of liquid ammonia can be calculated by the following curve-fitted equation which is based on data from three different sources:

$$\lambda = 1.4790 \times 10^{-3} + 2.2947 \times 10^{-6} T - 1.1726 \times 10^{-8} T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{cal cm}^{-1} \text{s}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. A curve calculated from this equation is shown in Figure 23, also in comparison to the Sellschopp equation which gives slightly higher numbers.

**Figure 22:** Anomaly of thermal conductivity of ammonia in the vicinity of the critical point (Reprinted and modified from [73], with permission from ©1965 Elsevier; permission conveyed through RightsLink)

This equation and the illustration in Figure 23 show a decrease of thermal conductivity with increasing temperature, whereas older literature data reported an increase of the thermal conductivity of liquid ammonia with temperature. For comparison, the thermal conductivity of liquid hydrazine also decreases with temperature. There is a wide discrepancy with up to 20% spread between the data from Needham and Ziebland [73], Golubev and Sokolova [74] and Richter and Sage [72]. Additional uncorrected thermal conductivity data are widely scattered and are not considered reliable [75].

The thermal conductivity of gaseous and liquid ammonia was measured in the range 297–387 K and at pressures of up to 50 MPa [76]. The measurements were necessary for a fitting of the thermal conductivity surface in the density–temperature plane.

**Figure 23:** Thermal conductivity of saturated liquid ammonia. (Reproduced and modified from [22].)

Results were believed to be accurate to  $\pm 2\%$ . It was difficult to make a good comparison of these results with previous data because no full correlation of the thermal conductivity of ammonia has been completed. A preliminary assessment for the liquid phase indicated that agreement was reasonable over much of the range, with differences up to around 5% under certain conditions. Results from an earlier 1984 publication had to be revoked due to a systematic error in the measurements [77]. For the gas phase, an approximate extrapolation to atmospheric pressure can be made, and the results compared with recommended values where differences of  $\pm 3\%$  were observed.

A correlation of selected literature data on the EOS and thermal conductivity of ammonia provided a set of recommended data for the vapor pressure, density, and thermal conductivity of liquid and gaseous ammonia along the saturation line for a temperature range from 200 to 400 K as shown in Table 19.

In an effort to minimize interference by convection, a transient short-hot-wire method was used to measure the thermal conductivity of liquid ammonia at 284–354 K and 2–10 MPa [79]. The measured data are shown in Table 20. Compared with the calculated values from REFPROP 10.0, the average absolute deviation was  $-5.6\%$  and all the newly measured values were lower than those from REFPROP 10.0 which are based on old data from prior to 1988. See also [80] and [81].

**Table 19:** Recommended data for thermal conductivity of liquid and gaseous ammonia along the saturation line.

### 3.8.2 Thermal Conductivity of Gaseous Ammonia

It has long been known that the transfer of energy by polyatomic and polar molecules like ammonia is quite complex because of the presence of internal degrees of freedom and the possibility of resonant energy transfer in the latter. Available thermal conductivity values for ammonia at essentially atmospheric pressure can be presented as a function of reduced temperature as shown in Figure 24. The critical temperature used for creating this graph was  $T_c = 405.5$  K. The compressibility factor was  $z_c = 0.242$ . Results of five available sources from the literature have been used to produce a relationship that is opposite in curvature to that found to exist for monatomic and

**Figure 24:** Thermal conductivity of gaseous ammonia. (Reprinted and adapted from [67], with permission from ©1961 American Chemical Society; permission conveyed through RightsLink.)

diatomic gases when plotted on log–log coordinates [67]. This type of behavior has been exhibited in a similar study for the thermal conductivity of methane.

The thermal conductivity of gaseous ammonia as a function of temperature at atmospheric pressure is shown as a function of temperature in Figure 25. The smooth curve represents values corrected for convection. The values in the literature have been included for comparison.

Thermal conductivity of gaseous ammonia at a sub-atmospheric pressure of 24 kPa (180 mm Hg) has been measured over the temperature range 311–473 K (38–200 °C) by a hot-wire method [82]. The collision numbers for rotational relaxation  $Z_{\text{rot}}$  have been determined from the experimental data and were found to increase with a rise of temperatures.

The thermal conductivity of ammonia gas has been measured by a column method at low pressures of 12.9, 26.5, and 45.0 kPa over the temperature range from 358 to 925 K [83]. The experimental data were correlated by a polynomial equation:

$$\lambda = 5.237 \times 10^{-3} + 5.179 \times 10^{-4} T + 8.404 \times 10^{-7} T^2 + 1.557 \times 10^{-10} T^3$$

**Figure 25:** Thermal conductivity of gaseous ammonia at atmospheric pressure. (Reprinted and adapted from [72], with permission from ©1964 American Chemical Society; permission conveyed through RightsLink.)

where  $\lambda$  is thermal conductivity in  $\text{mW cm}^{-1} \text{K}^{-1}$  and  $T$  is in kelvin. For example, this equation at 373K gives a thermal conductivity of  $0.323 \text{ mW cm}^{-1} \text{K}^{-1} = 3.234 \text{E-06 W m}^{-1} \text{K}^{-1}$ . See also [74, 78].

### 3.8.3 Thermal Conductivity of Supercritical Ammonia

Thermal conductivity values at high, supercritical pressures and for the liquid state are difficult to obtain. High-pressure thermal conductivity data for ammonia are not plentiful. Limited experimental data on ammonia for both viscosity and thermal conductivity necessitated the use of the theory of Enskog for the calculation of these transport properties at elevated pressures [67]. The residual thermal conductivity  $k - k^*$  can be related directly to the reduced density  $\rho/\rho_c$  of ammonia as shown in Figure 26, where  $k^*$  is the thermal conductivity at moderate pressures and  $\rho/\rho_c$  is the density divided by the critical density.

Using a coaxial-cylinder apparatus, the thermal conductivity of ammonia was measured at pressures of up to 80 MPa along nine quasi-isotherms in the supercritical regime and one quasi isotherm below the critical temperature, and the results were compared to previous data [77]. A semi-empirical equation was proposed to correlate the data in the supercritical regime.

**Figure 26:** Relationship of residual thermal conductivity and reduced density of ammonia in the dense-phase region. (Reprinted and adapted from [67], with permission from ©1961 American Chemical Society; permission conveyed through RightsLink.)

### 3.9 Heat Transfer Properties of Liquid Ammonia

Heat transfer properties of liquid ammonia are important not only for the design of commercial refrigeration machinery, but also for that of regeneratively cooled rocket engines such as the ones flown in the high-altitude research plane X-15 [69].

As with many other coolants in regeneratively cooled rocket engines, it is important to know the upper limit of nucleate boiling. At the transition from nucleate boiling to film boiling, a cushion of vapor forms between the wall and the liquid, causing high temperature gradients and hot spots in the wall which may lead to burnout of the

chamber or the nozzle. During nucleate boiling, the wall temperature rarely exceeds 30 degrees (C or K) above the boiling temperature at the prevailing pressure. The wall temperature and the heat transfer are a function of liquid temperature, flow velocity, and pressure. The upper limit of the heat flux is often abbreviated with the symbol  $q_{ul}$ .

Numbers reported in the literature for  $q_{ul}$  without stating the inlet temperature of the liquid are suspect. One cannot always assume that the liquid is entering the system at room temperature [84]. The results illustrated in Figure 27, which does have the inlet temperatures listed properly, mean it is possible to use its data for comparison.

**Figure 27:** Heat transfer to liquid ammonia at the upper limit of nucleate boiling, as a function of pressure and flow velocity. (Reproduced and modified from [69].)

Figure 27 shows the heat transfer at the upper limit of nucleate boiling as a function of pressure, with three different curves for three different flow velocities. A maximum of heat flux was achieved at 6.18 MPa = 61 atm, which is 55% of the critical pressure. Above the critical point, one cannot establish an upper limit of nucleate boiling because the difference between the liquid phase and vapor phase ceases to exist.

Figure 28 shows that the heat transfer at different inlet temperatures increases linearly with the flow velocity.

The upper limit of nucleate boiling heat transfer is a linear function of the initial inlet temperature of the liquid ammonia in the supply tank, as shown in Figure 29.

The slope of the linear function is dependent on the initial temperature of liquid ammonia in the reservoir. Figure 29 shows the upper limit of nucleate boiling of ammonia for various flow velocities as a function of the initial fluid temperature.

The heat transfer coefficient of liquid ammonia at the upper limit to nucleate boiling is low in comparison to other rocket propellants which might also be used as coolants in regenerative rocket engines (Table 21).

**Figure 28:** Heat transfer to liquid ammonia at 3.43 MPa = 34 atm as a function of flow velocities at different inlet temperatures. (Reproduced and modified from [69].)

**Figure 29:** Heat transfer to liquid ammonia at the upper limit of nucleate boiling, as a function of inlet temperature and flow velocity at a pressure of 3.43 MPa = 34 atm. (Reproduced and modified from [69].)

**Table 21:** Heat transfer coefficient of ammonia in comparison to other rocket propellants.

| Coolant liquid                | Heat transfer coefficient $q_{ul}$ at 2.07 MPa = 20.4 atm,<br>9.1 m/s and 310.9 K = 37.8°C inlet temperature |                                       | Heat capacity at<br>310.9 K = 37.8°C |                                      |

<sup>a</sup> The fuel used in the Corporal ballistic missile consisted of 80 mass-% aniline and 20 mass-% furfuryl alcohol

Data source: [84]

Besides its dependence on heat transfer properties, the suitability of a rocket propellant as a coolant in a regeneratively cooled rocket engine depends also on its heat capacity, on the difference between inlet temperature and the boiling temperature under cooling-jacket (pressure) conditions, and on the mixture ratio and the heat of reaction of the propellant combination. Calculations showed that ammonia as a regenerative coolant is barely capable of accepting the heat flux through the engine chamber wall of a 22.5-ton-thrust rocket engine operating on liquid oxygen (LOX)/NH<sub>3</sub> or red-fuming nitric acid (RFNA)/NH<sub>3</sub> [84]. In this comparison, the component listed first is the one used for regenerative cooling. In a comparison of RFNA/unsymmetrical dimethylhydrazine (UDMH), RFNA/Corporal missile fuel, RFNA/ diethylene triamine (DETA) or N<sub>2</sub>O<sub>4</sub>/JP-3, liquid ammonia did not emerge as a promising coolant. This is in spite of its relatively high heat capacity in comparison to the other fluids listed in Table 21. Ammonia's relatively low boiling point cancels out some of its advantages. Additional information on heat transfer to ammonia appears in the older technical publications summarized in Table 22.

Heat transfer experiments with anhydrous ammonia were conducted in a forced-convection apparatus [85]. The heart of the apparatus was an electrically heated, stainless-steel tube 4.8 mm O.D. × 0.25 mm wall thickness (3/16 in. O.D. × 0.010 in. wall thickness), mounted concentrically with a 7.9 mm I.D. (5/16 in. I.D.) heavy-walled Pyrex tube. The fluid under investigation flowed in the annulus between the two tubes. The heated section of the stainless-steel tube was 5 cm (2 in.) long. Auxiliary equipment included high-pressure storage and receiver tanks; a heat exchanger to regulate the bulk temperature of the fluid; a 20-kW direct-current generator (synchronous motor-driven) to supply the heater current; a Potter flowmeter to measure the fluid flow rate; thermocouples to measure heater-tube and bulk fluid temperatures; Tabor pressure transducers to measure system pressure and pressure drop across the heater; strip chart recorders to make simultaneous records of heater

voltage and current, pressures, temperatures, and flow rate; and the necessary piping, valves, and controls. Gas pressure was applied to the storage tank to force the fluid through the test section. Current was applied to the heater tube in stepwise increments until tube burnout occurred, or until the maximum output of the generator had been reached. At maximum generator output, the heat flux from the heater tube was about  $19610954 \text{ W m}^{-2}$  at 1.8 MW ( $12 \text{ BTU in.}^{-2} \text{ s}^{-1}$  at  $6200000 \text{ BTU/h}$ ). A total of 36 test runs was made with anhydrous ammonia. During these tests, the system pressure was varied from 3.1 to 4.14 MPa (from 450 to 600 psia), the bulk temperature from 275 to 326 K (from 35 to 127 °F), and the velocity from 6.7 to 38 m/s (from 22 to 125 ft/s). The annulus width was 1.57 mm (0.0618 in.) in all tests, giving a flow area of  $0.313 \text{ cm}^2$  ( $0.0486 \text{ in.}^2 = 0.000338 \text{ ft}^2$ ) and an equivalent hydraulic diameter of 3.137 mm (0.1235 in. = 0.01029 ft). Burnout always occurred suddenly, without any visual or instrumented warning. There was no stable film-boiling region. The Dittus-Boelter equation used for data correlation is:  $\text{Nu} = 0.027 \text{ Re}^{0.8} \text{ Pr}^{0.4}$ . Figure 30 presents typical uncorrelated results of test runs, with the heat flux ( $q/A$ ) plotted versus the temperature difference ( $T_w - T_f$ ) on log-log paper. The slopes of the lines in the non-boiling region should all be equal to unity. The zero intercepts of these lines should give values of the heat transfer coefficient,  $h$ , which is a function of velocity. The curves showed a sharp upward break at the inception of nucleate boiling, and, at higher values of  $q/A$ , the wall temperature remains nearly constant. This break occurred at a temperature of only 2–10 °F above the boiling point of ammonia at the system pressure.

Figure 31 shows a plot of the burnout heat flux versus  $\Delta T_{\text{sub}}$ , with fluid velocity as the parameter. These data have been compared with data published by the Jet Propulsion Laboratory (JPL). The JPL data show a lower dependence of ( $q/A$ ) burnout on  $\Delta T_{\text{sub}}$  than is shown on these results.

Forced-convection heat transfer in liquid ammonia in a smooth Inconel tube of 3-mm I.D and 3.5-mm O.D., a 300-mm length was measured at 0.5–10 MPa (5–100 bar), flow rates of 40–500  $\text{g s}^{-1} \text{ cm}^{-2}$ , inlet temperatures of 306–368 K (33–95 °C), heat fluxes of up to 315  $\text{W/cm}^2$ , and maximum wall temperatures of 1123 K (850 °C) [86]. The correlation

$$\text{Nu} = C \text{ Re}^{0.8} \text{ Pr}^{0.4}$$

was found to be applicable with a constant  $C$  of 0.021. Table 22 gives a summary of additional publications on the heat transfer to liquid ammonia. This is a starting point for future in-depth study of this topic.

Data source: [25]

A theoretically based crossover model, which incorporated a crossover from singular thermodynamic behavior at the critical point to regular thermodynamic behavior far away from the critical point, was derived for the thermodynamic properties of ammonia [95]. The equation was capable of representing the thermodynamic properties of ammonia between 398 and 500 K in an appreciable range of densities around the critical density. The crossover EOS was constructed so that it could be used in conjunction with the classical EOS developed by Tillner-Roth et al., which worked well outside the critical region. The new crossover EOS was compared with the widely used EOS for ammonia developed earlier by Haar and Gallagher.

### 3.11 Solubility, Miscibility, Mixtures, and Solutions of Ammonia

#### 3.11.1 Solubility of Pressurant Gases in Liquid Ammonia

The solubility of the pressurant gases nitrogen and helium in liquid ammonia is illustrated in Figure 32, based on data from Cannon 1968.

**Figure 32:** Solubility of pressurant gases in liquid ammonia. (Reproduced and modified from [22].)

Solubilities and Henry's coefficients of hydrogen, nitrogen, and oxygen in liquid ammonia at 293 K decrease in the given order [96]. Enthalpies of solution are slightly positive.

At very high pressures, would reactions between dihydrogen and ammonia lead to a new compound

A study of the composition of the gas phase in heterogeneous mixtures of hydrogen and ammonia at pressures of up to 41 MPa (6000 psia) in the temperature interval between 278 and 394 K (40 and 250 °F) indicated that the hydrogen/ammonia system behaved according to the conventional pattern of inert binary systems, in which there is no significant chemical reaction between the components [97, 98].

With nitrogen instead of hydrogen, at very high pressures, would reactions between dinitrogen and ammonia lead to a new compound

A similar study of the composition of the gas phase in heterogeneous mixtures of nitrogen and ammonia at pressures of up to 31 MPa (4500 psia) in the temperature interval between 278 and 394 K (40 and 250 °F) indicated that the nitrogen/ammonia system behaved according to the conventional pattern of binary systems, in which there is no significant chemical reaction between the components [99, 100].

### 3.11.2 Solubility of Ammonia in Water

The solubility of ammonia in water must be known for the design of scrubbers that must absorb ammonia when venting pressurized tanks, or absorbing excess ammonia in the exhaust of rocket engines working with hydrazine, or resistojets and arc jets operating on ammonia as a working fluid. In the latter case, ammonia should theoretically be completely decomposed after passing through the arc discharge, but some ammonia may escape during startup and shutdown.

At room temperature and atmospheric pressure, the saturation concentration of ammonia in water is approximately 30 mass-%  $\text{NH}_3$ .

The solubility of ammonia in water also enters the equations for the diffusion of ammonia spills in moist atmospheres, where some of the released ammonia may precipitate from the high-humidity atmosphere in the form of water/ammonia droplets.

Ammonia/water chillers take advantage of the solubility of ammonia in water and the heat released upon condensation (on the radiator) or heat absorbed (on the evaporator inside the refrigerator). See also [101–106].

### 3.11.3 Solubility of Salts in Liquid Ammonia

Ammonia is a frequently used non-aqueous solvent and a lot of chemistry has been conducted with ammonia as the solvent. The high solubility of ammonium thiocyanate or ammonium nitrate in liquid ammonia is well known, and the solutions, stable at room temperature and atmospheric pressure, are commonly referred to as Divers' solution R ("R" from the German *rhodanide*, the name for thiocyanate) and Divers' solution N. The vapor pressure of ammonia is reduced by dissolving these ammonium salts to a point where the liquids can be handled at atmospheric pressure at room temperature, but the loss of ammonia under these conditions is very fast.

The solubility of other nitrates in liquid ammonia has been tested in an effort to develop lower-vapor-pressure fuels or even monopropellants. The solubility of tetramethylammonium nitrate in liquid ammonia at 243 K ( $-30^{\circ}\text{C}$ ) is very low, only 0.4 g/100 mL solution, not sufficient for a monopropellant. In the same series, it was found that sodium acetylide had a surprisingly high solubility in liquid ammonia, 5.12 g/100 mL solution [107].

Solutions of lithium boranate,  $\text{LiBH}_4$ , in liquid ammonia have been patented as rocket propellants [108]. Lithium boranate forms adducts with ammonia in stoichiometric compositions, containing one or two ammonia molecules:  $\text{LiBH}_4 \bullet \text{NH}_3$  or  $\text{LiBH}_4 \bullet 2\text{NH}_3$ . The addition of  $\text{LiBH}_4$  would make liquid ammonia hypergolic with dinitrogen tetroxide (NTO), white-fuming nitric acid (WFNA), or RFNA.

### 3.12 Thermodynamic Properties of Ammonia

With the extensive use of ammonia as a refrigerant and heat transfer fluid, the thermodynamic properties have been thoroughly investigated and are widely published. One can find elaborate tabulated and graphed data of enthalpy–entropy charts, also known as  $h$ – $s$  charts or Mollier diagram in the literature.

Additional summaries of the thermodynamic properties of ammonia are compiled in the publications listed in Table 25.

**Table 25:** Publications on thermodynamic properties of ammonia.

| Author                  | Year | Type of data                     | References |
|-------------------------|------|----------------------------------|------------|
| NBS                     | 1923 | Thermodynamic properties         | [109]      |
| Din (Ed.)               | 1956 | Thermodynamic functions of gases | [110]      |
| Stull                   | 1964 | JANAF thermochemical tables      | [111]      |
| Muraca (Ed.)            | 1963 | Pressurized gas systems          | [38]       |
| Illinois Inst. Technol. | 1966 | Pressurized gas systems          | [112]      |
| Haar                    | 1968 | Thermodynamic properties         | [113]      |
| Haar and Gallagher      | 1978 | Thermodynamic properties         | [57]       |
| Edison and Sengers      | 1999 | Critical point properties        | [95]       |

The Helmholtz function of ammonia in the fluid state was represented by an analytic model function [114]. The model function has been fitted to experimental data as well as to specific heat capacities, vapor pressures, saturated-liquid densities, enthalpies of vaporization, and an experimental value of the critical temperature. The best values of the model parameters were found from the minimum of the sum of squared residuals by a non-linear regression procedure using a modified Marquardt sub-routine.

### 3.12.1 Heat Capacity of Ammonia

The heat capacity of gaseous ammonia can be calculated from the Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$ , A, B, C, D, and E are constants, and  $\tau$  is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 26. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor (see Sections 3.12.2 and 3.12.6). These equations were curve-fitted from data covering ranges from 298 to 1400 K and from 1400 to 6000 K.

Table 27 is a summary of the specific heat of the two-phase equilibrium saturated liquid ammonia.

**Table 26:** Constants for vapor-phase thermodynamic properties of ammonia.

| Temperature range, K | 298–1400  | 1400–6000 |
|----------------------|-----------|-----------|
| A                    | 19.99563  | 52.02427  |
| B                    | 49.77119  | 18.48801  |
| C                    | −15.37599 | −3.765128 |
| D                    | 1.921168  | 0.248541  |
| E                    | 0.189174  | −12.45799 |
| F                    | −53.30667 | −85.53895 |
| G                    | 203.8591  | 223.8022  |
| H                    | −45.89806 | −45.89806 |

Data source: [24]

**Table 27:** Specific heat of two-phase equilibrium saturated liquid ammonia.

| Temperature |        | Heat capacity                   |                                    |
|-------------|--------|---------------------------------|------------------------------------|
| K           | °C     | $\text{J g}^{-1} \text{K}^{-1}$ | $\text{cal g}^{-1} \text{°C}^{-1}$ |
| 319.47      | −46.32 | 4.4049                          | 1.0528                             |
| 311.83      | −38.68 | 4.4409                          | 1.0614                             |
| 302.38      | −29.23 | 4.4760                          | 1.0698                             |

| 285.85      | −12.7  | 4.5388                          | 1.0848                             |
| 274.48      | −1.33  | 4.5878                          | 1.0965                             |
| 264.43      | 8.72   | 4.6380                          | 1.1085                             |
| 254.50      | 18.65  | 4.6957                          | 1.1223                             |
| 250.33      | 22.82  | 4.7275                          | 1.1299                             |
| 244.68      | 28.47  | 4.7681                          | 1.1396                             |
| 234.98      | 38.17  | 4.8480                          | 1.1587                             |
| 227.23      | 45.92  | 4.9258                          | 1.1773                             |

Data source: [39]

The temperature dependence of the specific heat of solid ammonia can be calculated from the polynomial equation [23]

$$c_p = -0.040675 + 3.9238 \times 10^{-3}T$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{K}^{-1}$  and  $T$  is the absolute temperature in kelvin. The data in Figure 33 are from Overstreet and Giauque [23].

**Figure 33:** Heat capacity of frozen ammonia. (Reproduced and modified from [22].)

The temperature dependence of the specific heat of liquid ammonia can be calculated from the polynomial equation based on data from Overstreet and Giauque [23] and [115, 116]:

$$c_p = 0.062839 + 0.011328T - 4.5591 \times 10^{-5}T^2 + 6.5877 \times 10^{-8}T^3$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{K}^{-1}$  and  $T$  is the absolute temperature in kelvin (Figure 34).

Figure 34: Heat capacity of liquid ammonia. (Reproduced and modified from [22].)

### 3.12.2 Enthalpy of Formation and Heat of Combustion of Ammonia

The vapor-phase excess enthalpy above the standard enthalpy of formation  $\Delta H_f^{\circ, 298}$  of  $\text{NH}_3$  can be calculated from the Shomate equation:

$$H^\circ - H_{298.15}^\circ = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - \Delta H_f^{\circ, 298}$$

where A, B, C, D, E, and F are constants and  $\tau$  is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 26. The same coefficients (and others) were used for a formula expressing the heat capacity of the vapor (see Section 3.12.1). These equations were curve-fitted from data covering a range from 298 to 6000 K.

Table 28 is a summary of literature data for the enthalpy of formation of solid, liquid, and gaseous ammonia.

**Table 28:** Enthalpy of formation ( $\Delta H_f^{298}$ ) of ammonia.

| Physical state | Enthalpy of formation |       |                   |       | References |
|----------------|-----------------------|-------|-------------------|-------|------------|
|                | SI units              |       | Other units       |       |            |
|                | kJ/mol                | J/g   | kcal/mol          | cal/g |            |
| Gas            | $-45.94 \pm 0.35$     | -2697 | $-10.97 \pm 0.08$ | -644  | [24]       |
|                | -46.19                | -2712 | -11.04            | -648  | [117]      |
| Liquid         | -69.45                | -4078 | -16.6             | -975  |            |
|                | -71.54                | -4201 | -17.098           | -1004 | [118]      |
|                | -68.64                | -4030 | -16.4             | -963  | [24]       |
| Solid          | -74.3                 | -4362 | -17.7             | -1043 | [24]       |

Molecular mass: 17.0305 g/mol; 58.718 mol/kg

### 3.12.3 Heat of Fusion and Solid-State Phase Transitions of Ammonia

Data for the heat of fusion ( $\Delta H_{\text{fusion}}$ ) of frozen ammonia are summarized in Table 29.

**Table 29:** Heat of fusion of frozen ammonia.

| Heat of fusion  |                  |       |         | References |
|-----------------|------------------|-------|---------|------------|
| kJ/mol          | kcal/mol         | kJ/kg | kcal/kg |            |
| 5.966           | 1.426            | 350.3 | 83.73   | [119]      |
| 5.774           | 1.380            | 339.0 | 81.03   | [120]      |
| $5.655 \pm 0.8$ | $1.3516 \pm 0.2$ | 332.1 | 79.36   | [23]       |

Molecular mass: 17.0305 g/mol; 58.718 mol/kg

Overstreet and Giauque [23] reported an average from three separate determinations for the heat of fusion of frozen ammonia and calculated it as  $5.655 \pm 0.8 \text{ kJ/mol} = 1351.6 \pm 0.2 \text{ cal/mol}$ , a value that was considered accurate enough to be included in [22].

### 3.12.4 Heat of Vaporization of Ammonia

The heat of vaporization ( $\Delta H_{\text{vap}}$ ) of liquid ammonia at its normal boiling point of  $239.73 \text{ K} = -33.42^\circ\text{C}$  was measured and reported as  $23.35 \text{ kJ/mol} = 5.581 \text{ kcal/mol}$  [23].

The somewhat antiquated data on the heat of vaporization by Osborne and van Dusen 1918 were the most accurate data for many decades, and are still quoted in the literature today. The curve shown in Figure 35 is based on data from references [121] and [122]. The data can be curve-fitted by the polynomial equation

$$\Delta H_{\text{vap}} = 5.3115 + 0.013307T - 5.1012 \times 10^{-5}T^2$$

where  $\Delta H_{\text{vap}}$  is the heat of vaporization in kcal/mol and  $T$  is the temperature in kelvin.

**Figure 35:** Latent heat of vaporization of liquid ammonia. (Reproduced and modified from [22].)

The standard reference for the physical properties of ammonia and many other chemicals has been the National Bureau of Standards (NBS) circular *Tables of Thermodynamic Properties of Ammonia* (1923), in use for over 50 years until an update was published [57]. Nowadays, the best and most up-to-date data on the thermodynamic properties of ammonia and many other chemicals are available from the *NIST Chemistry WebBook* website [24] and the affiliated website listing properties of gases that are also used in semiconductor processing.

Haar and Gallagher correlated the vapor pressures obtained by Cragoe, Meyers, and Taylor [52], Beattie and Lawrence [53], and Keyes and Brownlee [54] by an equation containing five empirical constants. The differences between this equation and that of Baehr, Garnjost, and Pollak were minor [56]. Below 340 K, both equations correlated the data with the same accuracy. Larger deviations appeared at higher temperatures, where Baehr, Garnjost, and Pollak's equation closely followed the newer measurements which were not available to Haar and Gallagher.

The physical and thermodynamic properties of gaseous ammonia data in Table 30 were downloaded from the National Institute of Standards and Technology (NIST) website [123], where B and C are the 2<sup>nd</sup> and 3<sup>rd</sup> virial coefficients in the EOS.

**Table 30:** Physical and thermodynamic properties of gaseous ammonia.

| $T$ | $C_p(T)/R$ | Vapor pressure | $B(T)$                                                                   | $dB/dT \cdot T$               | $C(T)$                        | $\lambda$ | $\eta$           |

Data source: [123,124]

The heat of vaporization based on data measured at 293–392 K was listed as 22.7 kJ/mol at 308 K [47]. New data for a fundamental EOS for ammonia were compiled [125].

Only few industrial processes, including rocket propulsion, would require thermodynamic data for ammonia for the temperature range extending from the triple point to 750 K, and for the pressure range extending from the dilute gas to 500 MPa (5000 bar). These conditions for the coexisting phases and even close to the liquid–vapor critical point might occur on the surface of Jupiter (if it has a surface), or on other large planets where ammonia prevails. Values for the thermodynamic and PVT properties reported in 189 references in the literature were correlated, curve-fitted, and tabulated at closely spaced intervals [57]. While this publication contains a lot of numerical data, it lacks a table with the best recommended data for the liquid and gaseous ammonia at the standard reference state of 101 kPa and 298 K. For the coexisting saturated liquid and gaseous phases at a pressure of 101 kPa, the following data in Table 31 can be read from the tables.

**Table 31:** Thermodynamic and PVT properties of liquid and gaseous ammonia at 101 and 1010 kPa.

| Pressure, bar                                       | 1         | 10        |
|-----------------------------------------------------|-----------|-----------|
| Temperature, K                                      | 239.5     | 297.9     |
| Temperature, °C                                     | –33.6     | 24.9      |
| Specific volume liquid, cm <sup>3</sup> /g          | 1.46636   | 1.65801   |

Data source: [57]

The vapor pressures of  $\text{NH}_3$  and  $\text{ND}_3$  have been used to estimate the molar enthalpies of vaporization of  $\text{NH}_3(\text{L})$  and of  $\text{ND}_3(\text{L})$  from the triple-point temperatures to 290 K via the Clapeyron equation, using the Wagner equation to give the required values of  $dp/dT$  [40]. The molar enthalpy of vaporization of  $\text{ND}_3$  exceeded that of  $\text{NH}_3$  throughout this range. The difference amounted to about 3.5% at the triple-point temperatures, and decreased with rising temperature. The estimate of 23375 J/mol for  $\Delta H_{\text{vap}}(\text{NH}_3)$  at its normal boiling temperature agreed with the value of  $(23351 \pm 38)$  J/mol obtained calorimetrically by Overstreet and Giauque. The difference in the enthalpies of vaporization of  $\text{NH}_3$  and  $\text{ND}_3$  decreased from -1313 to -602 J/mol while the temperature increased from 200 to 270 K. Streatfeild et al. used Wagner's equation:

$$\ln\left(\frac{p}{p_c}\right) = (a_0\tau + a_1\tau^{1.5} + a_2\tau^3 + a_3\tau^6)/T_r$$

where  $T_r = T/T_c$ ,  $\tau = (1 - T_r)$  and  $p_c$  and  $T_c$  were the critical pressure and critical temperatures:  $\ln(p_c/\text{kPa}) = 9.33717$ , and  $T_c = 405.5$  K. The parameters had the values:  $a_0 = -7.20816$ ,  $a_1 = 1.23966$ ,  $a_2 = -2.3783$ , and  $a_3 = -1.528$ .

### 3.12.5 Heat of Combustion of Ammonia

When calculating the heat of combustion of ammonia, it is misleading to use the reaction

which results in a heat of combustion of gaseous ammonia of 292 kJ/mol = 69.9 kcal/mol. This reaction may take place on the surface of platinum catalysts. Instead, one must assume that the reaction goes to nitrogen and water

See Table 32.

**Table 32:** Heat of combustion of ammonia.

| Ammonia,<br>physical state                            | Combustion product |          |                       |                      |
|-------------------------------------------------------|--------------------|----------|-----------------------|----------------------|
|                                                       | kJ/mol             | kcal/mol | kcal/kg $\text{NH}_3$ | BTU/lb $\text{NH}_3$ |
| <b>Liquid water (upper heat of combustion)</b>        |                    |          |                       |                      |
| Liquid                                                | 357.2              | 85.386   | 5.014                 | 9024                 |
| Gaseous                                               | 382.8              | 91.505   | 5.373                 | 9671                 |
| <b>Water vapor (steam) (lower heat of combustion)</b> |                    |          |                       |                      |
| Liquid                                                | 291.2              | 69.607   | 4.087                 | 7357                 |
| Gaseous                                               | 316.8              | 75.73    | 4.446                 | 8004                 |

### 3.12.6 Entropy of Ammonia

The vapor-phase standard entropy of formation of  $\text{NH}_3$  can be calculated from the Shomate equation:

$$S^\circ = A \ln(\tau) + B\tau + \frac{C\tau^2}{2} + \frac{D\tau^3}{3} - E/(2\tau^2) + G$$

where  $S$  is the entropy in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $A$ ,  $B$ ,  $C$ ,  $D$ ,  $E$ , and  $G$  are constants and  $\tau$  is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 26. Some of these coefficients (and others) were used earlier for a formula expressing the heat capacity or the enthalpy of formation of the vapor (see Section 3.12.1). These equations were curve-fitted from data covering a range from 298 to 1500 K. For comparison, the entropy of gaseous ammonia at 298 K is  $192.77 \pm 0.05 \text{ J mol}^{-1} \text{K}^{-1} = 46.07 \text{ cal mol}^{-1} \text{°C}^{-1}$ .

### 3.13 Molecular Structure and Molecular Orbital Calculations of Ammonia

Ammonia,  $\text{NH}_3$ , is the lowest member of the family of hydronitrogens. The next-higher member of the family of hydronitrogens, hydrazine,  $\text{N}_2\text{H}_4$ , is more widely used as a rocket propellant than ammonia; it will be discussed in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine” in detail, along with other hydronitrogens.

The ammonia molecule forms a shallow trigonal pyramid, with bond angles of  $106.7^\circ$ , as opposed to the  $109.5^\circ$  of a methane tetrahedron (Figure 36). The lone electron pair repulses the other electrons, flattening the pyramid.

Figure 36: Molecular structure of ammonia

The nitrogen in the ammonia molecule can flip through the plane formed by the three hydrogen atoms and readily undergoes nitrogen inversion at room temperature. A popular analogy to this inversion is an umbrella turning itself inside out in a strong wind. The energy barrier to this inversion is  $24.7 \text{ kJ/mol}$ , and the resonance frequency is  $23.79 \text{ GHz}$ , corresponding to microwave radiation of a wavelength of  $1.260 \text{ cm}$ . The absorption at this frequency was the first microwave spectrum to be observed with radio telescopes. It is also observed in the interstellar gas.

### 3.13.1 Computational Chemistry of the Ammonia Molecular Structure

Because the ammonia molecule is symmetrical and relatively simple, there have been many studies predicting its vibrational energies using computational methods, but only a few will be referenced here as a starting point for further studies. Such calculations are useful to predict the spectral properties and enthalpies of formation of ammonia and other hydronitrogens. Linear Combination of Atomic Orbitals (LCAO) molecular orbitals have been calculated for the ground states of  $\text{NH}$ ,  $\text{NH}_2$ , and  $\text{NH}_3$  at various bond angles, using the LCAO self-consistent-field method [126]. Interactions between all electrons have been considered, and the orthogonality relationship between the  $1s$  orbitals of nitrogen and hydrogen was assumed.

*Ab initio* coupled cluster calculations have been carried out for the electronic ground state of ammonia [127].

Fourier transform infrared (IR) absorption and XRD experiments on equimolar mixtures of ammonia and water showed the formation of an ammonia monohydrate compound that spontaneously converted into an unusual crystalline state at high pressure in a diamond anvil cell at 25 GPa, where the standard molecular forms of water and ammonia coexisted with hydroxyl and ammonium ions [128]. The structure of the ammonia-ice compound was confirmed by *ab initio* molecular dynamics simulations. Such compounds are likely to exist in the interior of large gaseous planets like Jupiter.

### Bond Energies of Ammonia

The dissociation of  $\text{N-H}$  bonds in ammonia can be initiated by thermal, ultraviolet (UV) radiation, or X-ray radiation energy input or under electron bombardment in a glow discharge. The bond energies of  $\text{N-H}$  bonds decrease with increasing stepwise destruction (hydrogen abstraction and dehydrogenation) of the molecule, as shown in Table 33.

**Table 33:** Bond energies in ammonia.

| Bond            | Dissociation energy |             |              | References |
|-----------------|---------------------|-------------|--------------|------------|
|                 | kJ/mol              | kcal/mol    | eV           |            |
| $\text{H-NH}_2$ | $443 \pm 13$        | $106 \pm 3$ | $46 \pm 1.3$ | [129]      |
| $\text{H-NH}_2$ | $435 \pm 8$         | $104 \pm 2$ | $45 \pm 0.9$ | [130]      |
| $\text{H-NH}$   | $368 \pm 17$        | $88 \pm 4$  | $38 \pm 1.7$ | [130]      |
| $\text{H-N}$    | $368 \pm 25$        | $88 \pm 6$  | $38 \pm 2.6$ | [130]      |

### 3.13.2 Dipole Moment of Ammonia

Data for the dipole moment  $\mu$  of ammonia are summarized in Table 34.

**Table 34:** Dipole moment of ammonia.

| Dipole moment<br>Debye | References |
|------------------------|------------|
| 1.470                  | [24]       |
| 1.52                   | [8]        |
| 1.437                  | [131]      |
| 1.47149 and 1.47179    | [132]      |
| $1.468 \pm 0.009$      | [133]      |

### 3.13.3 Ammonia Dimers

Due to the intense intermolecular hydrogen bonding, ammonia molecules form dimers in the vapor phase. Dimers in the vapor phase and polymers in the liquid phase effectively reduce the vapor pressure of ammonia in comparison to non-associating fluids like liquid methane. The dimers can be detected by their IR spectrum which differs from that of the freely spinning molecule. Wherever ammonia exists on extraterrestrial bodies, part of it is likely to exist in the form of its dimer. Based on measurements of the quadrupole hyperfine structure, also in comparison to those of  $\text{ND}_3$  and its dimer, the structure of the dimer has been found to be asymmetric and quite different from what was previously assumed [134, 135]. It was previously thought that, in the dimer, one  $\text{NH}_3$  unit of hydrogen bonds to the other with a nearly linear  $\text{N}-\text{H}\cdots\text{N}$  arrangement, but the measured bond angles were quite different. The dissociation energy of the  $(\text{NH}_3)_2$  dimer has been estimated as less than 11.7 kJ/mol (2.8 kcal/mol).

Ammonia in the vapor phase may form ion clusters  $(\text{NH}_3)_n$ , up to  $n = 5$ , see reference [136]. These clusters can be fragmented by electron impact ionization in molecular beams. In 1992, a debate evolved about the structure of ammonia dimers based on results obtained with far-IR vibration-rotation-tunneling (FIR-VRT) spectroscopy. Measurements indicate that two ammonia molecules can form a “cyclic” dimer structure instead of the traditionally assumed  $\text{N}\cdots\text{H}$  linear hydrogen bond.

VRT splittings have been computed for the dimer  $(\text{NH}_3)_2$  by the use of four different model potentials which have different barriers to internal rotations, the interchange of the donor, and the acceptor in the hydrogen bond [137]. Dipole moments, nuclear quadrupole splittings, and the amount of quenching of the monomer umbrella inversions were computed, and good agreement with the experimental data available for  $(\text{NH}_3)_2$  was obtained, also for the observed change in the dipole moment upon isotope substitution.

### 3.14 Optical Properties of Ammonia

#### 3.14.1 IR Absorption Spectra of Ammonia

The IR spectrum of ammonia (Figure 37) is one of the most thoroughly examined spectra of all small molecules. It has some unique features that help to explain intermolecular hydrogen bonding, inversion oscillations, and dimer formation.

**Figure 37:** IR spectrum of ammonia. (Reproduced and modified with permission from [138])

The ammonia molecule has four normal vibration frequencies, two of which are doubly degenerate:  $\nu_1 = 3335\text{ cm}^{-1}$  (single);  $\nu_3 = 948\text{ cm}^{-1}$  (single) and  $\nu_4 = 1631\text{ cm}^{-1}$  (double). The value of  $\nu_2$  is in some doubt since it has not been observed spectroscopically. It is known to be large, however, and therefore of least importance to the partition function. IR band assignments are listed in Table 35.

**Table 35:** Vibrational and/or electronic energy levels of ammonia.

| Sym.  | No. | Approximate type of mode | Selected IR frequency |                  |                     |
|-------|-----|--------------------------|-----------------------|------------------|---------------------|
|       |     |                          | $\text{cm}^{-1}$      | $\text{cm}^{-1}$ |                     |
| $a_1$ | 1   | Sym stretch              | 3337                  | 3336.2           | symmetric level     |
| $a_1$ | 1   | Sym stretch              | 3337                  | 3337.2           | antisymmetric level |
| $a_1$ | 2   | Sym deform               | 950                   | 932.5            | symmetric level     |
| $a_1$ | 2   | Sym deform               | 950                   | 968.3            | antisymmetric level |
| $e$   | 3   | Deg stretch              | 3444                  | 3443.6           | symmetric level     |
| $e$   | 3   | Deg stretch              | 3444                  | 3443.9           | antisymmetric level |
| $e$   | 4   | Deg deform               | 1627                  | 1626.1           | symmetric level     |
| $e$   | 4   | Deg deform               | 1627                  | 1627.4           | antisymmetric level |

Data source: [24]

Symmetry:  $C_{3v}$ ; Symmetry number  $\sigma = 3$

### 3.14.2 UV Absorption Spectra of Ammonia

The UV absorption of ammonia is an essential step in the photochemical synthesis of hydrazine from ammonia, a reaction that may also take place in the atmosphere of Jupiter. The discrete absorption spectrum of ammonia has been photographed from 2300 to 850 Å [139]. The bands down to 1665 Å are all diffuse because of predissociation. Below 1665 Å, all the bands are very sharp and show a rotational fine structure which is partly resolved. True continuous absorption (distinct from that produced by pressure broadening) does not begin until about 1200 Å. At 1150 Å and below, the continuous absorption is so strong that no more bands could be measured accurately. Sharp bands exist, however, at least as far down as 1085 Å. The UV absorption spectrum of ammonia starts absorbing only at wavelengths below 210 nm [140].

### 3.14.3 Index of Refraction of Liquid Ammonia

The index of refraction of liquid ammonia at 289.6 K (16.5 °C) is  $n_D^{16.5} 1.325$  [39].

## 3.15 Microwave Spectra of Ammonia

Ammonia gas is known to exhibit a strong microwave absorption in the region of  $1.25 \text{ cm} = 0.8 \text{ cm}^{-1}$ . The inversion of the flat  $\text{NH}_3$  prism where the nitrogen atom swings through the plane of the three hydrogen atoms like an umbrella inverted in a gust of wind is characterized by its microwave absorption at  $0.8 \text{ cm}^{-1} = 23.69448 \text{ GHz}$  (inversion,  $J = 1, K = 1$ ). This wavelength has been one of the main operating frequencies of radio astronomers looking for ammonia on other planetary bodies, comets, and in interstellar space. The lines shift when the pressure of ammonia is increased.

## 3.16 Electrical Properties of Liquid Ammonia

### 3.16.1 Electrical Conductivity of Liquid Ammonia

The electrical conductivity of liquid ammonia (at  $194 \text{ K} = -79^\circ\text{C}$ ) is  $1.3 \times 10^{-7} \text{ Ohm}^{-1} \text{ cm}^{-1}$  [39].

Ammonia has been considered as a non-aqueous electrolyte and fuel in batteries and fuel cells where thiocyanate or sulfide would be added to increase the conductivity [141–143].

The solution of metals like lithium in liquid ammonia drastically increases its electrical conductivity, approaching that of the metals themselves. The solutions are dark blue from the cloud of free electrons which are the prime carriers of electricity (see Section 9.1).

### 3.16.2 Dielectric Constant of Ammonia

Data for the dielectric constant of liquid ammonia are listed in Tables 36 and 37 and are illustrated in Figure 38.

**Table 36:** Dielectric constant of ammonia.

| Temperature |      | Dielectric constant <sup>a</sup> |
|-------------|------|----------------------------------|
| K           | °C   |                                  |
| 196         | -77  | 25.4                             |
| 223         | -50  | 22.7                             |
| 288         | +15  | 15.9                             |
| 293.6       | 20.5 | 15.55                            |
| 297.6       | 24.5 | 14.9                             |

<sup>a</sup> liquid,  $\nu = 4.2 \times 10^8$  Hz, from [39]

**Figure 38:** Dielectric constant of saturated liquid ammonia. (Reproduced and modified from [22].)

**Table 37:** Dielectric constant of ammonia.

| Temperature, K  | 278          | 288          | 298          | 308          | 213 ± 10 |

Data source: [144]

An electric dipole moment function of  $\text{NH}_3$  was determined by fitting to experimental data (Stark splittings, absorption intensities) and to *ab initio* calculated dipole moment values using the non-rigid inverter Hamiltonian approximation [145]. The dipole moment function was used to calculate transition moments of some low-lying rovibrational states of symmetric isotopomers of  $\text{NH}_3$ . A close reproduction of the available experimental data was achieved which indicated that the predicted values were reliable.

### 3.17 Magnetic Properties of Ammonia

*Ab initio* calculations of the diamagnetic susceptibility of the ammonia molecule were performed by using gauge invariant atomic orbital methods [146, 147]. The results were  $\chi_{zz} = -14.64 \times 10^{-6}$  cgs units (along the molecular symmetry axis) and  $\chi_{xx} = \chi_{yy} = -14.94 \times 10^{-6}$  cgs units. The total predicted susceptibility was  $-14.84$  cgs units, which differed by 9% from experimental data  $-16.3 \pm 0.8$  cgs units [148].

The magnetic properties of ammonia change dramatically if alkali metals are dissolved in it, making it pseudo-metallic with good electrical conductivity.

## 4 Chemical Properties of Ammonia

Ammonia dissolves rapidly in water, forming alkaline solutions which contain a small fraction of ammonium hydroxide in equilibrium with physically dissolved, but chemically unreacted ammonia. Often bottles containing aqueous ammonia solutions are mislabeled “Ammonium Hydroxide.” Water saturated with ammonia at room temperature contains 30 mass-%  $\text{NH}_3$ , partially in the form of ammonia hydrate or ammonia dihydrate, but the concentration of undissociated ammonium hydroxide ( $\text{NH}_4\text{OH}$ ) is only very small.

Ammonia gas in air forms a white smoke with acid fumes (e.g., HCl fumes); this is a frequently used primitive method to detect ammonia leaks in a plumbing system if no more sophisticated electronic leak detection equipment is available.

#### 4.1 Chemical Reactions of Ammonia

Neutralization of aqueous ammonia solutions with acids forms ammonium salts which crystallize out after the solvent is evaporated. For rocket and gas generator applications, the most important ammonium salts are ammonium perchlorate (see *Encyclopedia of Oxidizers*, chapter “Perchlorate Oxidizers”) and ammonium nitrate (see chapter “Nitrate Oxidizers”).

##### 4.1.1 Reactions of Ammonia with Alkali Metals

Alkali metals and earth alkaline metals dissolve in liquid ammonia to form an intensely blue-colored solution. Such solutions are not very stable. In particular, those formed by the higher atomic number metals (cesium and rubidium) decompose gradually, forming a metal amide and hydrogen gas:

This reaction is accelerated by traces of catalytically active contaminants, e.g. salts of transition metals, e.g.  $\text{Fe}(\text{NO}_3)_3$ . Solutions of small concentrations of lithium in liquid ammonia are dark blue. In this regime, the solutions are not sensitive to oxygen in the air. Higher concentrations of lithium in ammonia give the solutions a metallic sheen, and are more sensitive to oxygen, and when the solutions are poured out in air, they throw sparks but will not ignite the ammonia. Concentrated solutions of lithium in ammonia are not very stable. They decompose within one month, and it is best to use them soon after preparation. See Section 9.1.2.

##### 4.1.2 Reactions of Ammonia with Alkali Metal Hydrides

The reaction of lithium hydride with water is a convenient source of hydrogen, but the reaction is not reversible. On the other hand, the reversible reaction of ammonia with lithium hydride forms lithium amide and gaseous hydrogen

This reaction has been investigated as a convenient source of hydrogen gas that can then be used as a fuel for fuel cells or inflating a balloon or other applications. The reaction is reversible, such that a canister of  $\text{LiH}/\text{NH}_3$  could be used as a hydrogen storage tank. After  $\text{H}_2$  generation by the reaction of  $\text{LiH}$  and  $\text{NH}_3$ , the byproduct  $\text{LiNH}_2$  can be recycled back to  $\text{LiH}$  under  $\text{H}_2$  flow and pressure conditions at 500 K [149, 150]. Transition metal chlorides were examined as a potential catalyst to improve the kinet-

ics. For the hydrogen desorption reaction, the reaction with a  $\text{TiCl}_3$  catalyst was about 8 times faster than the raw  $\text{LiH}$  [151].

#### 4.1.3 Reactions of Ammonia Borane with Alkali Metal Hydrides

Another source of hydrogen involving ammonia is the dry solid-state reaction of lithium hydride with ammonia borane ( $\text{NH}_3\text{BH}_3$ ) [152]. This material possesses a hydrogen capacity of around 10 mass-%, and can rapidly release over 7 mass-% pure  $\text{H}_2$ .

This reaction takes place during ball-milling at 293 K (20 °C), but can be suppressed when milling is conducted at the temperature of liquid nitrogen [153]. Cryomilling for 60 min reduced the reaction temperature from ~200 K (~70 °C) for unmilled powder to below room temperature, indicating that cryomilling can adjust the onset temperature for releasing hydrogen from solid materials that are thermodynamically unstable but with kinetic barriers. The reaction can be carried out in THF as a solvent/dispersant at 313 K (40 °C) [154].

#### 4.1.4 Reactions of Ammonia with Boron Hydrides

The reaction of ammonia with diborane forms an array of Lewis salt adducts. These compounds that may gain use as reversible storage media for dihydrogen gas will be discussed in the chapter “Boranes.”

#### 4.1.5 Reactions of Ammonia with Oxygen

There are two important reactions of ammonia with oxygen, one the simple combustion leading to nitrogen and water,

the other a catalyzed reaction leading to nitrogen dioxide

and, ultimately, nitric acid. The reaction of liquid ammonia with LOX was the main propellant in the X-15 hypersonic research plane.

#### 4.1.6 Reactions of Ammonia with Nitrogen Oxides

Reactions of ammonia with nitrogen oxides are used in the stack gas  $\text{DeNO}_x$  process for the removal of  $\text{NO}_x$  contaminants before the stack gases from fossil-fired powerplants are released into the atmosphere.

The combination of liquid dinitrogen tetroxide and liquid ammonia has been used in stationary rocket testing, producing a very clean, smokeless, transparent exhaust plume.

## 4.2 Thermal Stability of Ammonia

In the absence of catalysts, ammonia is thermally stable up to 673 K (400 °C). Above 673 K, it will decompose irreversibly into its elements nitrogen and hydrogen in a reversal of the industrial process by which it was made. This is an endothermic process and can be used to cool hot surfaces. When ammonia is used as a working fluid in electrothermal thrusters or arc jets, it will decompose, and the exhaust has a favorable low molecular mass due to the high content of hydrogen.

### 4.2.1 Decomposition Kinetics of Ammonia

The homogeneous gas-phase decomposition kinetics of ammonia over a wide range of pressures have been thoroughly investigated. This reaction limits the yield in commercial ammonia production. The rate of this reaction is a design parameter for electrothermal rocket engines operating on evaporated and dissociating gaseous ammonia. This reaction is part of the decomposition of hydrazine, an important monopropellant.

### 4.2.2 Homogeneous Gas-Phase Decomposition Kinetics of Ammonia

Homogeneous gas decomposition kinetics are studied mostly at low pressures and in shock tubes. The kinetics of ammonia decomposition (catalyzed or not) have been thoroughly studied for a variety of reasons. The main reason is that the decomposition of ammonia is a limiting factor in the synthesis of ammonia from its elements, a vital industrial process. If ammonia in the cooling jacket of a regeneratively cooled rocket engine overheats, it may decompose and form a two-phase gas/liquid mixture which would have different properties of heat transfer and pressure drop through an orifice.

The homogeneous rate of decomposition of  $\text{NH}_3$  in  $\text{NH}_3$ -Ar mixtures containing 1% and 8%  $\text{NH}_3$  in Ar was measured in a shock tube behind reflected waves [155]. The initial rate of decomposition of  $\text{NH}_3$  in Ar has been measured between 2000 and 3000 K by following the rate of decrease of emission intensity in the 2.7- to 3.2- $\mu\text{m}$  wavelength region. The measured activation energy of about 217.6 kJ/mol (52 kcal/mol) did not match the bond energy of breaking the first  $\text{H}_2\text{N}-\text{H}$  bond of 439 kJ/mol (105 kcal/mol). There must be more than one reaction occurring.

One of the ammonia dissociation products is imine ( $\text{NH}$ ). Mixtures of ammonia in xenon were shock-heated to temperatures in the range 2900–9600 K and the radiation from  $\text{NH}$  was monitored at 3360 Å [156]. It was found that the production of  $\text{NH}(\text{A}^3\Pi)$

was second-order in the initial ammonia concentration within experimental error, and could be described by a rate constant

$$k = 4 \times 10^{-14} \exp\left(\frac{-54000}{T}\right) \text{cm}^3 \text{mol}^{-1} \cdot \text{s}^{-1}.$$

It was found that NH normally decayed at two different rates, one being half of the other.

#### 4.2.3 Catalytic Decomposition Kinetics of Ammonia

The kinetics of catalytic ammonia decomposition have been thoroughly studied for a variety of reasons. The main reason is that the catalytic decomposition of ammonia is a limiting factor in the synthesis of ammonia from its elements, a vital industrial process.

Another industrial application of catalytic ammonia decomposition is in the creation of “furnace gas,” a mixture of nitrogen and ammonia often used as a reducing protective atmosphere in industrial furnaces where metal parts that are sensitive to oxygen in the air are annealed or melted under exclusion of oxygen. The catalytic decomposition of ammonia is the most convenient method for generating hydrogen gas for use in air/hydrogen fuel cells.

The catalytic decomposition of ammonia is also a step in the multi-step decomposition of hydrazine as a monopropellant, where it takes place mostly in the downstream end of the catalytic reactor.

Catalysts capable of decomposing ammonia include ruthenium, rhodium, and palladium [157], platinum [158], and ruthenium and platinum alloys [159]. There are many commercial catalysts available for the dissociation (“cracking”) of ammonia to generate furnace gas or hydrogen. Furnace gas is used as a protective atmosphere for heat treatment (annealing) of refractory metals that are sensitive to air. Some contain Rh, Ru or Ir supported on  $\text{Al}_2\text{O}_3$  or  $\text{ZrO}_2$  [160].

If the hot dissociation products are passed through a palladium membrane tube, only hydrogen permeates through the membrane and exits in a very pure form suitable for use in fuel cells or other applications [161].

Ammonia decomposition catalysts are typically supported metal catalysts with alumina, ceria, or zirconia as the carrier material [162].

The catalytic decomposition of ammonia creates a gas mixture containing hydrogen gas that can immediately be used to convert energy in a fuel cell, most likely an air/hydrogen fuel cell. Waste heat from the fuel cell can be used to vaporize and pre-heat the ammonia before it enters the catalytic dissociation reactor. Nitrogen dilution reduces the electrode potential on the hydrogen side only moderately.

### 4.3 Photolysis of Ammonia

The UV absorption spectrum of ammonia starts absorbing only at wavelengths below 210 nm, with quantum yields of 0.25–0.45 [140]. The photolysis of ammonia is a process occurring on a cosmic scale in the atmosphere of Jupiter, potentially creating a small stationary concentration of hydrazine in a dynamic equilibrium. Photolysis of ammonia has been studied as a means of making quantities of hydrazine, avoiding the use of hypochlorite or hydrogen peroxide as the oxidant.

### 4.4 Radiolysis of Ammonia

Ammonia decomposes under the influence of ionizing radiation (X-rays, gamma rays, and electron beams) and forms amidogen free radicals  $\cdot\text{NH}_2$ . Amidogen radicals can either decompose to nitrogen and hydrogen, or recombine to form hydrazine. This has been studied as a potential route to produce anhydrous hydrazine in large quantities. Chapters 1.2.2 and 1.2.6 in the author's book *Hydrazine and Its Derivatives*, 2<sup>nd</sup> ed [163], contain a thorough summary of the radiolysis of ammonia leading to various products, mostly aiming for hydrazine.

Radiolysis of ammonia also occurs in the atmosphere of Jupiter where there appears to be an equilibrium of ammonia, with ammonia forming by a yet to be identified mechanism at the same rate as it is decomposed by ionizing radiation. Radiolysis of ammonia in the atmosphere may result in the formation of a small, stationary concentration of hydrazine which would decompose just as fast as it might have formed. It has been theorized that some of the white clouds of frozen ammonia in the atmosphere of Jupiter might contain frozen hydrazine.

There is concern that continued radiolysis of ammonia might not only produce hydrazine but also hydrazoic acid, which would immediately combine with ammonia to form ammonium azide; this would remain in solution in liquid ammonia and create a new hazard in the residue after all the ammonia has evaporated.

### 4.5 Storage Stability of Ammonia

Ammonia is stable at room temperature. Liquid or gaseous ammonia can be stored indefinitely at room temperature. Liquid ammonia at its boiling point at atmospheric surface-level pressure should not be allowed to stand open in the laboratory because it would quickly absorb carbon dioxide and water from the air and its boil-off causes a respiration hazard.

## 4.6 Analysis and Quality Control of Ammonia

### 4.6.1 Detection of Ammonia in Air

Ammonia leakage needs to be detected in the refrigeration compressor rooms of cold-storage warehouses and anywhere where liquid and aqueous ammonia are used as agricultural fertilizer. Ammonia is also an exhaust product of hydrazine monopropellant rocket engines and gas generators, for instance those used in F-16 fighter-plane emergency power units (EPUs) and Space Shuttle auxiliary power units (APUs), and would be detected downwind of these airplanes and spaceplanes while the gas generators are operating.

Nessler's reagent is used as an aqueous solution to detect free ammonia and ammonium ions in water. Nessler's reagent is  $\text{HgI}_2$  in KI solution, mixed with 6-N NaOH immediately prior to use. The reaction with ammonia causes a brown precipitate of the iodide of Millon's base ( $\text{Hg}_2\text{N}$ )I. The Nessler's reagent method is often used as a semi-quantitative method with a nephelometer.

The pungent odor of ammonia is noticeable already at concentrations of 17 ppm, which is 68% of the threshold limit value time-weighted average (TLV-TWA) (25 ppm), such that special warning installations are not required. There are several instruments which are capable of continuous analysis of ammonia content in air and which can be set to a threshold concentration where they will trigger an alarm.

For occasional spot checks of ammonia concentration in air, the easiest method is with gas detection tubes which contain an indicator supported on a granular material, which changes color when exposed to ammonia. Such tubes are available from Draeger, MSA, "Kitagawa" etc. Gas detection tubes are sensitive to as little as 0.25 ppm  $\text{NH}_3$  and can measure up to 10 vol %  $\text{NH}_3$  with ten strokes with the manual-bellows pump. A more accurate and automated sampler is the chip, which combines ten capillary tubes on one small board. Draeger ammonia gas detection tubes and chip boards are available for a wide range of concentrations (Table 38).

The Draeger chip-measuring-system (CMS) is a self-contained unit that has a pump and a digital readout. Each disposable chip contains ten measurement capillaries filled with a substance-specific reagent system. The reactive preparations necessary for detection are kept in hermetically sealed glass capillaries until needed. When the chip is inserted into the analyzer, all information required for detection is transferred to the analyzer by means of a bar code:

- type of gas
- measuring range
- measuring time
- parameters for the calibration function
- required flow rate.

The analyzer records the measurement effect optoelectronically, thereby eliminating human error in reading a color scale. In the CMS, miniaturization has resulted in

**Table 38:** Draeger ammonia gas detection tubes and chip boards.

| Type              | Tube designation | Concentration range | Draeger part no. |
|-------------------|------------------|---------------------|------------------|
| Single tube       | ammonia 0.25/a   | 0.25–3 ppm          | 81 01 711        |
| Single tube       | ammonia 2/a      | 2–30 ppm            | 67 33 231        |
| Single tube       | ammonia 5/b      | 2.5–100 ppm         | 81 01 941        |
| Single tube       | ammonia 5/a      | 5–700 ppm           | CH 20 501        |
| Single tube       | ammonia 0.5%/a   | 0.05–10 Vol.%       | CH 31 901        |
| 10-capillary chip |                  | 0.2–5 ppm           | 64 06 550        |
| 10-capillary chip |                  | 2–50 ppm            | 64 06 130        |
| 10-capillary chip |                  | 10–150 ppm          | 64 06 020        |
| 10-capillary chip |                  | 100–2000 ppm        | 64 06 570        |

Data source: [164]

a reduction in the sample volume necessary for a measurement (compared to the manual-bellows pump with 10 strokes). For a typical measurement, only 30 mL of air is needed for a measuring time of approximately two minutes and a flow of 15 mL/min. The power needed for operation of the analyzer is provided by four AA batteries. After inserting the chip, an optical system calculates the number of remaining measurements still available on the chip being used, and displays this together with the gas type and the measuring range. Up to 50 measurement results can be stored in the machine with the name of the measured substance, the concentration, the date and time of the measurement, and a code letter to help identify the measurement location.

Nessler's reagent has been employed for the analysis of ammonia in air or water, but this method lacks sensitivity and suffers from a variety of interferences and reagent instability.

A direct, one-step method for the determination of ammonia (and primary aliphatic amines) is so rapid that instantaneous determinations may be made of the ammonia concentrations being sampled. The method requires collection of ammonia in a suitable neutral solvent (e.g. dioxane) containing (benzenesulfonamido)-p-benzoquinone, and measuring the absorption of light at 480 nm [165].

Ammonia vapor concentrations from 1000 to less than 60 ppm were easily, reproducibly, and reversibly detected by a glass capillary coated with a thin solid film of oxazine perchlorate dye [166].

#### 4.6.2 Assay Analysis of Ammonia

One of the main contaminants in liquid ammonia is water. Analysis of water contamination in liquid ammonia can be performed by a colometric method [167, 168].

Another contaminant in liquid ammonia is carbon dioxide, most likely present in the form of dissolved ammonium carbamate. Carbon dioxide in anhydrous liquid ammonia can be determined by a titrimetric method [169]. The carbon dioxide, com-

bined as ammonium carbamate, is separated from the ammonia by evaporation at or below room temperature, and is determined by acidification and absorption in barium hydroxide. Analysis of known-concentration CO<sub>2</sub>-doped samples in the range of 0 to 50 ppm CO<sub>2</sub> showed a precision of  $\pm 1.5$  ppm.

#### 4.6.3 Military Specifications for Liquid Ammonia

MIL-P-27406 Military Specification: Propellant, Ammonia dated 9 May 1966 was canceled on 26 June 1984. Future procurements for this material were advised to refer to Federal Specification O-A-445, dated 25 February 1975. O-A-445 went through several revisions until Rev. C, O-A-445C, Federal Specification, Ammonia, Technical, 15 pp. (6 Aug 2003) was released, which covered one grade of compressed anhydrous ammonia for refrigeration and nitriding purposes, but was canceled without replacement by Notice 1 dated 16 July 2010.

The purity requirement of O-A-445C was purity (min.) 99.98 mass-%, oil (max.) 0.0005%, and moisture (max.) 0.02%. Purity is the mass percent of ammonia by difference, when the mass percent of the residue remaining after evaporation at no more than 86°F (30 °C) is adjusted for absorbed NH<sub>3</sub> and subtracted from 100%. The remaining residue is a mixture of water, oil, non-volatile impurities, and ammonia. The water content of the residue can be determined by dissolving it in methanol and titrating with Karl Fischer reagent. The oil content of the residue is determined gravimetrically after extraction with carbon tetrachloride and evaporation of the solvent. When the ammonia was produced with hydrogen from a source other than natural gas, it had to be tested for pyridine, naphthalene, and hydrogen sulfide. Analytical methods for these tests are described in the specification. A document contains detailed instructions for determining moisture content in liquid ammonia [168].

## 5 Compatibility with and Corrosion of Materials in Ammonia

Dry anhydrous ammonia is not very corrosive and can be used in contact with many metallic or non-metallic materials of construction.

### 5.1 Metallic Construction Materials for Ammonia

Most metals are compatible with dry, anhydrous ammonia. Stainless steel is resistant, even to moist ammonia, whereas copper, brass, zinc, magnesium, and their alloys must be avoided. Cast-iron components galvanized with zinc or cadmium should not be used because the coatings will peel off.

The preferred metals of construction for ammonia installations are the stainless steels of the 300 and 400 series. Storage tanks, pipes, pumps, valves, and pressure gauges are made from stainless steel. One must be careful that valves and pressure gauges do not have any copper-containing parts.

There are some contradictory recommendations about the contact of ammonia with mercury, as this would often occur in laboratory glass equipment in low-pressure apparatus with mercury U-gauge manometers. Some sources warn against contacting metallic mercury with ammonia because a reaction might lead to explosive and shock-sensitive mercuric azide [170] (but this has not been confirmed). Mercury diffusion pumps in high-vacuum systems should not be operated when ammonia is passed through the pump with hot mercury.

## 5.2 Non-Metallic Construction Materials for Ammonia

Gaskets, O-rings, and valve stem packings for ammonia service are made from Teflon, Kel-F, or asbestos-impregnated fluorocarbon polymers. Polyethylene is rarely used, but can be.

## 5.3 Lubricants for Ammonia Service

Common hydrocarbon-based lubricants are not suitable for liquid ammonia service because they are quite soluble in liquid ammonia. Perfluorinated greases, such as Kel-F Polymer Oil, Fluorolube, and silicon grease have been recommended. One must be aware that many chlorofluorocarbon refrigerants react with liquid ammonia. The author has observed a near-explosive delayed runaway reaction of a mixture of liquid ammonia and liquid FC-22 in a closed steel vessel. After venting the residual vapor, the tank was filled with a white solid, probably a mixture of ammonium chloride and ammonium fluoride. There are cooling circuits on spacecraft where heat is transferred between ammonia and chlorofluorocarbons. One must avoid any leakage and mixing between the two fluids.

# 6 Handling of Ammonia

Recommendations for the safe handling of liquid ammonia were published by several trade associations, including the Compressed Gas Association [171–173].

An excellent study was conducted in Denmark on the handling safety of ammonia as a fuel for general public automobiles as a replacement for gasoline and in comparison to other alternatives such as liquified natural gas (LNG), liquified petroleum gas (LPG), methanol, and compressed hydrogen [174]. The study addressed the safety of

operating an ammonia-powered vehicle under normal and accident (collision) conditions, of transporting ammonia to the refueling service stations, and of the activities at the refueling service station (bulk delivery unloading and refueling of consumers' cars). The conclusion was that the hazards associated with ammonia need to be controlled by a combination of technical and regulatory measures. The most important requirements are:

- Advanced safety systems in the vehicle
- Additional technical measures and regulations to avoid the release of ammonia in maintenance workshops and unauthorized maintenance of the fuel system.
- Road transport of ammonia to refueling stations in refrigerated form
- Sufficient safety zones between refueling stations and residential or otherwise public areas.

When these measures are applied, the use of ammonia as a transport fuel would not cause any more risks than currently used fuels (using current practice).

## 6.1 Storage of Ammonia

Ammonia is usually stored as a compressed liquid in steel containers at room temperature under its own vapor pressure. The vapor pressure of liquid ammonia at room temperature (298 K) is  $1003 \text{ kPa} = 9.895 \text{ atm} = 145 \text{ psig}$ .

Some ammonia storage cylinders for laboratory use have two valves, one to withdraw gas from the vapor space above the liquid and the other connected to a dip tube that allows one to withdraw liquid ammonia under pressure.

When transferring liquid ammonia from one container to another, e.g. a run tank at a rocket test site, one must be careful not to overfill the receiving tank. Because ammonia often cools during transfer due to evaporation, the liquid is dense and gradually expands as it warms up again after the transfer. If the ullage space is insufficient to accommodate the expansion of the liquid, the tank may overpressurize and burst.

If several liquid ammonia storage containers are placed together, and the tanks are not all at the same temperature (only rarely the case, e.g. if one side of the spacecraft is facing the sun), the liquid will flow from the warmest tank to the coldest tank. In a satellite, this would cause a shift in the center of gravity and the spinning satellite may become unstable. The other hazard would be overfilling one of the tanks and then closing a valve, causing the tank to overpressurize when the liquid expands upon warming.

Ammonia gas is lighter than air. It may accumulate under the roofline in closed buildings and become a flammability hazard.

## 6.2 Transfer of Ammonia

Liquid ammonia needs to be transferred between transportation tanks and stationary farm tanks. Transfer of liquid ammonia can be performed by three different methods: under its own vapor pressure, with a pressurant gas, or with a positive-displacement pump.

The first method is suitable only for small containers and small quantities. The vaporization of ammonia to fill the new vapor space above the liquid will cool the remaining liquid to a point where flow will soon cease due to a lack of differential pressure. A standing cylinder will form a ring of frost on the outside, which some people welcome as an unsophisticated means of liquid level indication. Users are advised not to attempt to speed the evaporation in tanks with frost rings by immersing them in hot water or heating them with open flames. Such one-sided heating might cause thermal stresses in the container and leaks or ruptures.

If high delivery rates of liquid ammonia are needed, it is better to pressurize the tank with an inert pressurization gas, typically nitrogen, and pressure-feed the contents from the source tank. One must not use compressed air for the pressurant gas because air and ammonia form combustible and explosive mixtures. If even higher delivery rates are needed, particularly in large installations, the liquid must be transferred with pumps. Pumps for liquid ammonia service are typically made from stainless steel.

Liquid ammonia was present on every Space Shuttle flight where it was used as dump coolant to provide cooling of the crew compartment during aerodynamic heating upon re-entry. Liquid ammonia is currently present on the ISS where it is used as a closed-loop heat transfer fluid. It remains in the liquid state (and is thus not a compressor/evaporator loop as in commercial refrigeration units).

The ISS contains two active thermal control sub-systems that function by using a liquid-ammonia cooling system to collect waste heat and dispose of it in space using radiator panels [175]. These sub-systems consist of a number of heat exchangers, cold plates, radiators, the pump flow control sub-assembly (PFCS), and the pump module, all of which are orbital replaceable units. The PFCS circulates the ammonia coolant in the photovoltaic thermal control sub-system (PVTCS), and has been in operation since December 2000. The pump module circulates liquid ammonia coolant within the external active thermal control sub-system (EATCS), cooling the ISS internal coolant (water) loops, collecting waste heat, and rejecting it through the ISS radiators. These pump module loops have been in operation since December 2006, but not without problems. Original reliability predictions of the PFCS and pump module were compared against the operational performance of the ISS external thermal control loops.

## 6.3 Components for Ammonia Service

### 6.3.1 Ground Support Equipment and Fueling Carts for Liquid Ammonia

Ground support equipment (GSE) included an ammonia fueling cart developed for the Electric Propulsion Space Experiment [176].

### 6.3.2 Flight Tanks

A liquid-ammonia propellant feed system for operating under zero-gravity conditions in a satellite with electrothermal resistojet thrusters contained a regulator/capillary tube assembly which controlled the propellant delivery pressure and assured that only vapor was delivered to the thruster [177]. The system demonstrated the capability of maintaining a pressure control dead band of  $\pm 6.9$  kPa ( $\pm 1$  psi) at a delivery pressure of 138 kPa (20 psia) with either liquid or vapor extracted from the tank. See also [178–180].

### 6.3.3 Couplings

A rotary shut-off ammonia fluid quick-disconnect coupling for ISS Alpha was a precursor to couplings later used on the ISS [181]. This is a dual-line coupling consisting of two halves, an active and a passive one, mounted on separate structures within the same system. Similar couplings could be used for ground servicing of reusable rockets (like the X-15) that use ammonia as a consumable fuel. These couplings on the ISS have caused repeated problems [182].

## 6.4 Accidental Ammonia Spills

### 6.4.1 Accidental Ammonia Spill Vapor Cloud Dispersion

A study of the behavior of ammonia which has escaped into the atmosphere as a result of accidental failure of a pressurized-liquid container showed that the formation of a cold ammonia/air mixture, which is denser than the surrounding air, is very likely [183]. As a result, gravity-driven phenomena must be taken into account, e.g. the cloud slumps and becomes very broad. It was shown that this slumping is insensitive to assumptions made about the rate of entrainment of the air and the rate at which the mixture is heated by the ground. It was also demonstrated that, unless the wind speed is very low, the dispersing ammonia may not become buoyant. This is another phenomenon that is insensitive to parameter variations. See also [184–187].

A large number of reports of incidents involving the accidental release of ammonia were studied and combined into a model that would allow one to predict the consequences of short-term exposure to high concentrations of gaseous ammonia [188].

Sixteen different source types were modeled including pressurized-liquid releases, flashing and aerosol formation, two-phase jet releases, explosive releases,

and releases of high-vapor-pressure liquids, cryogenic liquids, and gases [189]. Dispersion models took into account the differences in source strengths and higher-than-air density of clouds (due to aerosol presence, temperature, or molecular weight). The reactions of the chemicals with water vapor in the atmosphere were modeled and included in the dispersion model. The transition from heavy-gas dispersion to near-neutral density dispersion was modeled without abrupt changes in size or discontinuity in concentrations.

Potential atmospheric and human health impacts that may result from accidental releases of anhydrous ammonia were evaluated using a traditional Gaussian puff model [190]. Dense two-phase aerosol releases from a 68-m<sup>3</sup> (18000-gallon) liquefied-ammonia storage tank and a 22.7-m<sup>3</sup> (6000-gallon) tanker truck accident were evaluated by means of the refined vapor dispersion model, SLAB. The SLAB results were compared to those using the neutral-buoyancy puff model. A SLAB sensitivity analysis was presented which examined various combinations of ambient temperatures and wind speeds in order to determine worst-case downwind air concentrations. The results from the storage tank releases indicated that potentially serious ammonia concentrations (>1000 ppm) could result at downwind distances ranging from 150 m (relief-valve malfunction) to approximately 3 km (catastrophic tank failure). The tank failure scenario produced concentrations that could be rapidly fatal (>5000 ppm) to as far as 1.3 km. Under worst-case meteorological dispersion conditions, the recognized exposure limits, i.e. Immediately Dangerous to Life and Health (IDLH), TLV-short-exposure limit (STEL) were exceeded for very large distances (>15 km).

The US Air Force and the American Petroleum Institute, among others, have increased the emphasis on calculating toxic corridors due to releases of hazardous chemical into the air. Dozens of PC-based computer models were recently developed to calculate these toxic corridors. However, the uncertainties in these models have not been adequately determined, partly due to the lack of a standardized quantitative method that could be applied. Individual model developers generally present a limited evaluation of their own model, and the US Environmental Protection Agency (EPA) has published some partial evaluations, but no comprehensive study has yet been completed. A report provided examples of the application of air dispersion model software to 14 typical hazard response models and eight sets of field data [191].

#### **6.4.2 Controlled Ammonia Spill Tests**

Large-scale spill tests of ammonia and dinitrogen tetroxide were performed at the Nevada Test Site [192]. The tests were extensively instrumented, resulting in large amounts of data which can be used to quantitatively describe the observed atmospheric dispersion phenomena. Preliminary results from both test series indicated that aerosols play a very important role in the dispersion of dense gas. The test data were ideally suited for model validation, and several example model data comparisons were included. Gaussian model calculations were found to be

inadequate even at long distances downwind. Highly instrumented, controlled spill tests with large quantities of liquid ammonia were conducted at remote locations to better justify the limitations regarding liquid ammonia tanks being placed in the vicinity of residential areas [193].

## **6.5 Disposal and Ammonia Spill Neutralization**

### **6.5.1 Disposal of Surplus Ammonia**

As a result of replacing chlorofluorocarbons, that have ozone-depleting potential, as refrigerants with ammonia, many industrial installations have to consider the prospect of ammonia fires and have developed methods for the disposal of surplus ammonia in a flare burner in a controlled manner [194]. There may be new opportunities for catalytic reactors to clean up the exhaust gases from such burners, or to complete the ammonia destruction without  $\text{NO}_x$  formation and with a much lower consumption of natural gas in the flare stack.

### **6.5.2 Ammonia Spill Neutralization**

If liquid ammonia is spilled accidentally, it will initially evaporate quickly until the spill site has cooled to the boiling point of liquid ammonia ( $240\text{ K} = -33^\circ\text{C}$ ), and then more slowly depending on the spill area, the soil conditions, the ambient temperature, and the atmospheric conditions. The remaining puddle can be absorbed and diluted with water. Ammonia aerosol clouds can be absorbed by a fine spray of water mist. Ammonia absorbed into the soil at a spill site would gradually be consumed by natural processes (evaporation, leaching, mineralization, reacting with atmospheric carbon dioxide, and consumption by ammonia-oxidizing bacteria), similar to what happens in an ammonia-fertilized field.

## **6.6 Protective Clothing for Handling Ammonia**

Ammonia gas is very irritating to mucous membranes and will cause lacrimation. Liquid ammonia must be handled only by properly trained personnel wearing adequate protective clothing that consists of a face mask, goggles, a gas mask, and rubber gloves.

When handling liquid ammonia on a large scale, additional protective clothing includes aprons, helmets, and rubber boots. Gas mask filters are usually effective only against less than 3 vol.-% ammonia in air. At higher vapor concentrations, the operators must wear supplied-air ensembles.

## 7 Toxic Properties of Ammonia

The safety properties of ammonia are summarized in Table 39. The following information was taken from National Academies Press, Laboratory Chemical Safety Summaries [195].

**Table 39:** Safety properties of ammonia.

| Formula                  | NH <sub>3</sub>                                                   |
|--------------------------|-------------------------------------------------------------------|
| Physical properties      | colorless gas                                                     |
| Boiling point            | 240 K = -33 °C                                                    |
| Freezing point           | 195 K = -78 °C                                                    |
| Highly soluble in water  | 89.9 g/100 mL* at 0 °C                                            |
| Odor threshold           | intense pungent odor detectable at 17 ppm                         |
| Vapor density            | 0.59 (air = 1.0)                                                  |
| Vapor pressure           | 0.879 MPa at 294 K (8.71 atm at 21 °C)                            |
| Autoignition temperature | 963 K (690 °C)                                                    |
| Toxicity                 | LD50 oral (rat) 350 mg/kg<br>LC50 inhalation (rat) 2000 ppm (4 h) |
| PEL (OSHA)               | 35 ppm (27 mg/m <sup>3</sup> )                                    |
| TLV-TWA (ACGIH)          | 25 ppm (17 mg/m <sup>3</sup> )                                    |
| STEL (ACGIH)             | 35 ppm (27 mg/m <sup>3</sup> )                                    |

Ammonia gas is extremely corrosive and irritating to the skin, eyes, nose, and respiratory tract. Exposure by inhalation causes irritation of the nose, throat, and mucous membranes. Lacrimation and irritation begin at 130–200 ppm, and exposure at 3000 ppm is intolerable. Exposure to high concentrations (above approx. 2500 ppm) is life-threatening, causing severe damage to the respiratory tract and resulting in bronchitis, chemical pneumonitis, and pulmonary edema, which can be fatal. Eye contact with ammonia vapor is severely irritating, and exposure of the eyes to liquid ammonia or mists can cause serious damage, which may result in permanent eye injury and blindness. Skin contact with ammonia vapor, mists, and liquid can cause severe irritation and burns; contact with the liquid results in cryogenic burns as well. Ingestion of liquid ammonia burns the throat and pharyngeal tissues, causing severe abdominal pain, nausea, vomiting, and collapse, and can be fatal. Ammonia gas is regarded as having adequate warning properties. Ammonia has not been found to be carcinogenic or show reproductive or developmental toxicity in humans. Chronic exposure to ammonia can cause respiratory irritation and damage.

Ammonia inhalation toxicity is a matter of concern not only where ammonia is handled as such, but also downwind of testing rockets and gas generators with decomposing hydrazine operated on Earth, such as in F-16 EPUs. See also [196].

## 7.1 Symptoms of Ammonia Poisoning

The immediate response of mucous membranes of the nose and eyes to inhalation of ammonia gas in the air is lacrimation, increased saliva flow, and eye and nose irritation. At higher concentrations, the irritation causes reddening of the eyes, coughing fits, a feeling of suffocation, and vomiting. Even the sweat of a person suffering from acute ammonia poisoning and removed from the site of the accident will reek of ammonia. Most of the ammonia inhaled is retained in the lung; only 10% is exhaled again. Inhalation of a high concentration of ammonia may cause lung edema which can be fatal several days after the accident.

The body can gradually get used to higher and higher concentrations, such that even 200–300 ppm can be endured without lasting effects. The author once participated in a voluntary exposure experiment in a closed chamber with 500 ppm  $\text{NH}_3$  in air for 30 min. Lacrimation ceased 15 min after the start of the test.

Concentrations of 400–700 ppm cause immediate lacrimation and irritation of the respiratory tract, >1500 ppm causes strong coughing, >2000 ppm can cause permanent damage even after short exposure, and >5000 can be fatal after only a few breaths. Even if the subject is wearing respiratory protection, >10000 ppm will cause irritation of the skin, in particular in moist air and if the subject is sweating, and >30000 ppm can cause caustic burns and skin lesions.

## 7.2 Olfactory Threshold for Ammonia

The olfactory threshold for ammonia in air has been variously reported to be as low as 5 ppm and as high as 50 ppm. A frequently cited average is 20 ppm (0.015 mg/L).

Air monitoring data and human exposure reports were collected following a variety of accidental ammonia releases [197]. Of 65 readings between 1.1 and 1.5 ppm, odor was detected in 51 samples (78.5%). These data are consistent with an ammonia odor threshold within a concentration range of 1.1–1.5 ppm. This level is significantly lower than frequently cited historical data. Furthermore, a review of the ammonia literature demonstrated that the ammonia odor threshold is significantly lower than levels that produce eye, nose, or throat irritation.

## 7.3 Inhalation Toxicity of Ammonia

### 7.3.1 Inhalation Toxicity of Ammonia as Measured by Animal Exposure Tests

The acute inhalation toxicity of ammonia was examined in rats using various exposure concentrations and exposure periods [198]. Groups of male and female rats were exposed to dynamic atmospheres containing different concentrations of ammonia for 10, 20, 40, or 60 min. The aim of the study was to establish the relationship between

exposure concentration and exposure period on the one hand, and mortality on the other. The correlation between exposure concentration ( $c$ ), exposure period ( $t$ ) and mortality rate, expressed in probits was found to be  $\text{Probit} = 2.30 \ln [c^{2.02} \times t] - 47.8$ . The following  $\text{LC}_{50}$  values for ammonia were calculated: 10 min  $\text{LC}_{50}$  : 28130 mg/m<sup>3</sup> air (40300 ppm), 20 min  $\text{LC}_{50}$  : 19960 mg/m<sup>3</sup> air (28595 ppm), 40 min  $\text{LC}_{50}$  : 14170 mg/m<sup>3</sup> air (20300 ppm), 60 min  $\text{LC}_{50}$  : 11590 mg/m<sup>3</sup> air (16600 ppm). Experiments designed to determine an  $\text{LC}_{50}$  in mice from a 1-h exposure to  $\text{NH}_3$  followed by a 14-day observation period indicated that the  $\text{LC}_{50}$  was close to 18000 ppm [199].

### 7.3.2 Inhalation Toxicity of Ammonia as Measured by Human Volunteer Exposure Tests

Inhalation toxicity tests were conducted with healthy human volunteers under close medical surveillance. Sixteen subjects, eight experts (29–53 yr) and eight non-experts (students, 18–30 yr) were exposed for 2 h to ammonia in concentrations of 50, 80, 110, and 140 ppm [200]. No effect on vital capacity, forced exhaled volume 1 or forced inhaled volume 1 was found. Subjective responses (smell, irritation of eyes and throat, discomfort, etc.) were recorded every 15 min and appeared more pronounced in the non-expert group and 140 ppm was not tolerated by this group for 2 h.

Twelve healthy persons underwent sham or ammonia (5 and 25 ppm) exposure randomly in an exposure chamber on three occasions [201]. The exposure duration was 3 h, 1.5 h resting (seated), and 1.5 h exercising (50 W on a bicycle ergometer). Symptoms were registered repeatedly before, during, and after the exposure on visual analog scales. Bronchial responsiveness to methacholine, lung function, and exhaled nitric oxide (NO) were measured before and 7 h after the exposure. In addition, nasal lavage was performed, and peripheral blood samples were drawn before and 7 h after the exposure. All the symptom ratings increased significantly during 25-ppm ammonia exposure as compared with the control exposure. The ammonia exposure did not significantly influence lung function or the exhaled NO levels. Ammonia inhalation at the TLV did not cause detectable upper-airway inflammation or increased bronchial responsiveness to methacholine in healthy persons.

The author, in his younger years, once volunteered for a 500-ppm  $\text{NH}_3$  human volunteer exposure test of 30-min duration, and can report from his own experience that it was very uncomfortable.

## 7.4 Regulatory Exposure Limits for Ammonia

The governments of various countries have instituted different threshold limit values for exposure to ammonia at the workplace. The US Occupational Safety and Health Administration (OSHA) initially adopted an ammonia standard of 50 ppm as an 8-h TWA, based on the 1968 recommendation of the American Conference of Governmental Industrial Hygienists (ACGIH). In 1973, the ACGIH revised its recommended ammonia exposure limit to 25 ppm for 8-h TWA and added a 35-ppm, 15-min STEL to protect against irritant effects. In June 1988, OSHA proposed the adoption of these limits as legally enforceable standards, but concluded that the available evidence of chronic health effects was insufficient to support any 8-h TWA limit for ammonia.

In 1997, the National Advisory Committee on Acute Exposure Guideline Levels (NAC AEGL) proposed AEGL for ammonia as shown in Table 40 which were lower (more restrictive) than the levels recommended by the industry.

**Table 40:** Acute Exposure Guideline Levels (AEGL) for ammonia.

| AEGL                                      | Concentration (ppm-v) by exposure duration parameter |         |      |      |      |
|-------------------------------------------|------------------------------------------------------|---------|------|------|------|
|                                           | 5 min.                                               | 30 min. | 1 h  | 4 h  | 8 h  |
| NAC AEGL proposals                        |                                                      |         |      |      |      |
| 1                                         | 25                                                   | 25      | 25   | 25   | 25   |
| 2                                         | 380                                                  | 160     | 110  | 110  | 110  |
| 3                                         | 3800                                                 | 1600    | 1100 | 550  | 390  |
| RAM TRAC/Ammonia Industry recommendations |                                                      |         |      |      |      |
| 2                                         | 1704                                                 | 696     | 492  | 246  | 174  |
| 3                                         | 16869                                                | 6887    | 4870 | 2435 | 1722 |

Data source: [202]

The values were generally too low by a factor of approximately 4.5. An excellent summary of acute toxicity data of ammonia is given in [202]. Historical data suggesting that ammonia at 5000–10000 parts per million (volume/volume = ppm-v) might be lethal within 5–10 min were critically examined in view of more recent accident reconstructions that suggest that instant lethality requires higher ammonia concentrations. For example, 33737 ppm-vol. was a 5-min zero-mortality value in a major ammonia release accident in South Africa in 1973. Comparisons of secondary reports of ammonia lethality with original sources revealed discrepancies with contemporary sources. A survey revealed that contemporary accident reconstructions yield ammonia lethality levels comparable to those in dozens of reports of animal bioassays, after adjusting the concentrations to human-equivalent concentrations via US EPA procedures. Ammonia levels potentially causing irreversible injury or impairing the ability of ex-

posed people to escape from further exposure and concurrent perils have similarly been biased downwardly in contemporary sources. The EPA has identified ammonia as one of 366 extremely hazardous substances subject to community right-to-know provisions of the Superfund Act and emergency planning provisions of the Clean Air Act. The Clean Air Act defines emergency planning zones (EPZs) around industrial facilities that exceed a threshold quantity of ammonia on site. It was suggested that EPZs around ammonia facilities can be reduced, thereby also reducing emergency planning costs, which will vary roughly with the EPZ radius squared.

Criteria used in establishing acute AEGL were detailed in a National Research Council publication [203]. The 1987 National Research Council Emergency Exposure Guidance Levels (EEGLs) were: a 1-h EEGL of 100 ppm and a 24-h EEGL of 100 ppm. The original IDLH concentration (in standard cubic feet, SCF) for ammonia of 500 ppm was later (in 1994) revised to 300 ppm. The author has participated as a volunteer in a 500-ppm, 0.5-h exposure experiment with no lasting effects. See also [204, 205].

## 7.5 Liquid Ammonia Dermal Effects

Liquid ammonia spilled on the skin has a dual effect: a freezing frostbite effect and a caustic chemical burn effect.

In two cases of exposure to pressurized ammonia during an industrial accident, the skin conditions were quite different. One patient's symptoms were consistent with an ammonia alkali burn whereas the other patient's symptoms were more characteristic of a significant thermal injury caused by the rapid expansion and evaporation of a pressurized liquid [206].

As with any other alkali burns, early irrigation to remove the ammonia from the affected skin areas is crucial to limit tissue damage. Two cases of identical exposure to industrial-strength ammonia were presented and compared [207]. Each patient was exposed to ammonia liquid and vapors simultaneously when a tank containing this compound exploded. One patient showered at the scene immediately after exposure, but the other deferred irrigation until he arrived at the hospital. The first patient suffered minor burns with a 2-day, uncomplicated hospital stay. The second patient suffered 14% total body surface area burns and a significant inhalation injury. He required intubation, mechanical ventilation, and skin grafting during his 13-day hospitalization. Although much is written about the management of chemical burns, few articles address those caused by liquid ammonia. Aggressive initial management significantly reduces the morbidity of ammonia burns.

A 28-year-old patient suffered 45% total body surface area second- and third-degree burns as well as inhalational injury from an anhydrous ammonia explosion [208]. Along with fluid resuscitation, for the first 48 h, his body was scrubbed every 6 h with sterile water to decrease the skin pH, from 10 to 6–8. He subsequently underwent a total of seven wound debridements, initially with allograft and then

autograft. On post-burn day 45, he was discharged. The injuries associated with anhydrous ammonia burns are specific to the effects of ammonium hydroxide. Liquefactive necrosis results in superficial to full-thickness tissue loss. The affinity for mucous membranes of anhydrous ammonia and its byproducts can result in hemoptysis, pharyngitis, pulmonary edema, and bronchiectasis. Ocular sequelae include iritis, glaucoma, cataracts, and retinal atrophy. The desirability of treating anhydrous ammonia burns immediately cannot be overemphasized. Clothing must be removed quickly, and irrigation with water initiated at the scene and continued for the first 24 h. Resuscitative measures should be started as well as early debridement of non-viable skin. Patients with significant facial or pharyngeal burns should be intubated, and the eyes irrigated until a conjunctivae sac pH of <8.5 is achieved.

Severe ammonia injury is associated with high morbidity and mortality. One case report demonstrated the pathophysiology and treatment of both cutaneous burn wounds and inhalation injury caused by ammonia [209]. Frequent bronchoscopy was used to attempt to avoid intubation. The patient remained extubated, but later required skin grafts to close his wounds once his pulmonary injury had healed. Bronchoscopy can be a useful tool to avoid intubation.

Five patients with severe liquid ammonia injury after an explosion in a warehouse suffered severe inhalation and ophthalmic injuries, as well as cutaneous burns, representing the challenges inherent in simultaneously managing the dermal and pulmonary complications of this injury [210].

When treating ammonia accident victims, it is important to understand the influence of street clothing and environmental and other factors on the rate of ammonia absorption into the body. Ammonia was selected for *in vitro* human skin studies of absorption, penetration, and off-gassing at test concentrations of up to 2000 ppm, incorporating primary and secondary exposure combinations of up to 60 min [211]. Intact skin provided a good barrier to ammonia penetration from the gas phase. Human skin penetration was generally low for exposures up to 1000 ppm for 30 min. Heavy street clothing such as denim was found to act as an initial barrier to skin absorption but subsequently as a reservoir for secondary exposure, under variable temperature and humidity conditions. Rapid off-gassing was observed for lighter fabrics including polyester and cotton. In either case, contaminated clothing should be removed as soon as possible.

## 7.6 Ammonia Accident Statistics

In 2002, the US Poison Control Centers reported almost 6000 cases of toxic ammonia exposures: 93% of exposures were unintentional and 11% resulted in a moderate-to-severe outcome.

Unplanned releases of ammonia have led more often to evacuation and injury than releases of other chemicals, but few studies have systematically investigated

ammonia releases. A review of Hazardous Substances Emergency Events Surveillance system data for 1993–1998 revealed that 537 ammonia releases required the evacuation of a total of at least 40680 persons, and 248 ammonia releases led to the injury of 1434 persons [212]. Equipment failure and operator error were cited as factors contributing to ammonia releases 90% of the time. Eighty-seven percent of the releases occurred at fixed facilities. Risk factors for evacuation and injury differed between the food-manufacturing industry and other industries. Indoor release was a consistent risk factor, but the quantity of ammonia released was not always a risk factor. An ammonia leak in Crete, NE, USA, on 18 February 1969 caused 9 deaths and 53 injuries. In an accident on 11 May 1976 in Houston, TX, USA, a tanker truck crash released 17.2 tons of pressurized anhydrous ammonia. The chemical cloud extended 1500 m downwind and was 550 m wide. Five people were killed and 178 were injured, some with permanent disabling injuries. The fatalities and disabling injuries occurred within about 70 m of the accident. An ammonia leak in Lievin, France, on 21 August 1968 caused 5 deaths and 20 injuries. See also [213–216].

## 7.7 Other Ammonia Leakage Adverse Effects

Astronauts performing EVA to repair the ammonia cooling system on board the ISS may have spilled small amounts of ammonia on their suits and dragged the chemical into the air lock and the interior of the ISS when they returned from the EVA. In spite of the vacuum in outer space which would cause ammonia spills to evaporate quickly, some ammonia may adhere to the space suit. Another failure mode is an internal leak in the heat exchanger where heat from the low-pressure internal water loop is transferred to the high-pressure external ammonia loop [217].

### 7.7.1 Ammonia Accident History and Case Studies

Although ammonia is not currently used as a rocket propellant, the hazards of accidental release of ammonia are summarized in this section. This information may be useful in evaluating ammonia as a fuel for other applications. Individuals who are acutely exposed to high concentrations of ammonia and survive the immediate effects may die weeks to months later, probably due to the secondary effects of exposure. The lungs of an accident victim who died 2 months after exposure showed morphologic alterations [218]. Major pathologic findings included cylindrical bronchiectasis of the lower lobes and fibrous obliteration of the small airways.

A 25-year-old refrigeration technician died of obliterative bronchiolitis 85 days after an accidental massive ammonia inhalation [219]. Eighteen people died from accidental release of ammonia in South Africa [220]. The health status of a life-long non-smoker who was the victim of a massive accidental exposure to anhydrous ammonia gas was followed up for 10 years [221]. In the acute phase, the patient presented with

severe tracheobronchitis and respiratory failure caused by very severe burns of the respiratory mucosa. After some improvement, he was left with severe and fixed airways obstruction. Isotope studies of mucociliary clearance, computed tomography, and bronchography showed mild bronchiectasis. It was concluded that acute exposure to high concentrations of ammonia may lead to acute respiratory injury but also long-term impairment of respiratory function.

In a meat factory using liquid ammonia as a refrigerant, there was a breach in the refrigeration system caused by careless handling of the forklift truck by one of the factory workers. The penetrated pipe, part of the 2500-L refrigeration system, was located outdoors in the factory area and instantly started leaking. Factory personnel underwent immediate evacuation, except for a 20-year-old male worker who remained lying beside the broken pipe. He was not wearing protective gear. He had injuries to both eyes, second- and third-degree burns on his face, anterior neck, left axilla, left arm, part of the anterior and posterior chest wall, genitalia, and both lower limbs, i.e. covering a 50% total body surface area [222]. The initial chest radiograph showed congestion of both lung hiluses and perihilar vascular structures, with signs of swift development of acute respiratory distress syndrome seen on subsequent films. Severe inhalation injury was confirmed by bronchoscopy, revealing edema and reddish epithelium in the bronchial tree. The patient subsequently required a lung transplant; this is the first description of a case of successful lung transplantation after a massive anhydrous ammonia inhalation injury.

A tanker truck carrying anhydrous ammonia fell off a highway and released a dense cloud of ammonia aerosol. Fifty-four people were exposed to the gas. After 90 days, three people were still experiencing hoarseness and were examined, revealing laryngeal sequelae due to ammonia inhalation burn, one case of hyperemia and edema, one case of granuloma of the posterior third portion of the left vocal cord, and one case of vocal-cord adhesion [223].

Exposure to anhydrous ammonia can result in substantial injury to the respiratory system, eyes, and skin. Acute and chronic respiratory manifestations in 12 patients exposed to anhydrous ammonia as a result of the same accident were compared [224]. Survivors suffering significant ill effects were separated into two groups according to their history and clinical course. One group of patients sustained exposure to high concentrations of ammonia over a short period of time. They suffered upper airway obstruction and required early intubation or tracheostomy. These patients recovered with few pulmonary sequelae and regained good pulmonary health. The second group of patients were exposed to lower concentrations of gas over a prolonged period of time and did not manifest upper airway obstruction. In this group of patients, however, significant long-term pulmonary sequelae were observed.

A patient who had an accidental exposure to liquid ammonia over a prolonged period, manifesting in cutaneous, respiratory, and ocular damage, in addition to a severe cold thermal injury (frostbite), with a fatal outcome, had flaccid quadriplegia and

episodes of bradycardia [225]. These manifestations raise the possibility of the systemic toxicity in patients with prolonged exposure to ammonia.

Residents of Minot, ND, USA, were exposed to 200000 gallons of anhydrous ammonia after a train derailment caused the release of the chemical. The train derailment occurred just outside Minot on 18 January 2002, when a Canadian Pacific Railway freight train derailed in Harrison Township in Ward County, west of Minot, spilling hazardous materials [226]. All 15 tank cars carrying liquid ammonia derailed and five of these tank cars catastrophically ruptured, with an instantaneous release of about 146700 gallons of anhydrous ammonia and additional releases in the following days. Some of the breached tanks propelled themselves 1000 feet away from the railroad tracks. The liquid quickly turned into a gas and formed a toxic white aerosol cloud that engulfed most of the city, affecting more than 15000 people. One resident was fatally injured and 60–65 residents of the neighborhood nearest to the derailment site were rescued. As a result of the accident, 11 people sustained serious injuries and were hospitalized with respiratory, ocular, and burn injuries, and 322 people, including the two train crewmembers, sustained minor injuries. Local hospital and triage centers treated more than 300 people for respiratory and ocular injuries. See also [227].

#### **7.7.2 First-Aid Treatment of Ammonia Accident Victims**

Initial emergency response to ammonia accidents involves evacuation, decontamination, first aid, and alerting the appropriate authorities [228]. Decontamination must be complete and rescuers must avoid being overcome by fumes. Emergency department care is directed at respiratory, ocular, skin, and gastrointestinal treatment. Respiratory and ocular lesions tend to be the most severe and can be used as a triage guide. The need for a multi-disciplinary approach to hospital care is stressed. In severe exposures, adult respiratory distress syndrome is a common finding. In children who have ingested aqueous ammonia, early endoscopy, aggressive antibiotic therapy, and serial dilatations of strictures are recommended. Long-term complications occur predominantly to the eyes and respiratory tract.

In the case of accidental inhalation, the victim must be moved into the fresh air and a physician must be called to evaluate the case. In the case of respiratory failure, an oxygen mask should be kept at the ready to provide artificial respiration.

If liquid ammonia is spilled on the skin, the frostbite makes the caustic burns even worse, in particular after the tissue thaws out. First aid in the case of liquid ammonia spills on skin comprises flushing the affected area with copious amounts of water. Ammonia-soaked clothing must be removed. If ammonia has spilled into the eyes, they should be rinsed for at least 15 min in an eye-wash fountain and a physician must be consulted immediately. Some first aid instructors recommend a rinse with a dilute % boric acid solution.

## 8 Explosion and Fire Hazards of Ammonia

### 8.1 Flammable Range of Gaseous Air/Ammonia Mixtures

Ammonia forms flammable mixtures with air and other oxidants in a narrow range of concentrations, but is much less of a fire hazard than natural gas, propane, or gasoline. Ammonia fire hazards exist in lines and tanks that are being filled with ammonia without prior replacement of air by an inert gas like nitrogen. Ammonia fire hazards exist in buildings where an ammonia leak has occurred in the presence of ignition sources.

Air/ammonia mixtures are a potential hazard in refrigeration plants, where several accidents with ammonia explosions have been reported [229]. With the phasing out of fluorochlorohydrocarbons as the working fluids in refrigeration units, there will be an increase in the use of ammonia. The interest in accidental ammonia explosions and their prevention will continue for some time to come.

Non-flammable and non-detonable off-stoichiometric mixtures of oxygen and ammonia with or without inert diluent gases have been considered as propellants for catalytic microthrusters, but before such mixtures can be selected, the flammable range must be determined.

In flammable mixtures with borderline flammability, the convection as the result of the incipient combustion enhances flame propagation. These mixtures have a distinct difference in upward and downward propagation. Some (e.g. air/ammonia) burn upwards only. In Earth's orbit in a zero-gravity environment, these near-limit mixtures are self-extinguishing flames. This was demonstrated with air/ammonia and oxygen/hydrogen/nitrogen mixtures of borderline flammability under microgravity conditions [230].

Because ammonia in air has a very narrow flammable range, this mixture is well suited to demonstrate the dependence of flammable limits on the direction of propagation. In a gravity field, the buoyancy of the hot gases helps the upward propagation of the flame. Propagation of flames in a zero-gravity environment is a relatively new field of study. It appears that most flammable mixtures have very narrow ranges of flammability in a zero-gravity environment since the flame virtually suffocates in its own combustion products. Figure 39 illustrates the limits of flammability of ammonia in air as a function of the initial temperature and the direction of propagation of the flame in a 50-mm-diameter tube [231, 232]. It is interesting to note that ammonia in air cannot be made to burn downward until the mixture is pre-heated to 350 K.

The flammable range of air/fuel mixtures depends on the vessel geometry, direction of propagation, ignition energy, initial mixture temperature and pressure, and, most of all, on the oxidizer/fuel mixture ratio. Limits of flammability of flammable gases and vapors in air are generally reported for a 50-mm-diameter tube with upward propagation at 293 K = 20 °C and atmospheric pressure at sea level. The flame

**Figure 39:** Flammability of air/ammonia mixtures. Influence of temperature and direction of propagation of flame. (Reproduced and modified from [232].)

speed and critical diameters for air/ammonia flames such as those used in industrial combustors will be discussed in a future volume on non-hypergolic bipropellant combinations.

The limits of flammability of ammonia in dry air at 293 K = 20 °C with upward propagation are 16.1–26.8 vol.-% NH<sub>3</sub>. Other sources gave NH<sub>3</sub>/air at 293 K = 20 °C, 1 atm 15.5–28 vol.-% NH<sub>3</sub>, NH<sub>3</sub>/air at 373 K = 100 °C, 1 atm slightly widened limits from 14.5–29.5 vol.-% NH<sub>3</sub> and NH<sub>3</sub>/O<sub>2</sub> at 293 K = 20 °C, 1 atm distinctly widened limits from 13.5–82 vol.-% NH<sub>3</sub>.

The fire hazard during handling of ammonia is relatively low, compared to hazards when handling other fuels such as propane or gasoline, or even liquid hydrogen. The flammable range of ammonia burning in air with upward propagation is from 15 to 28 vol.-% NH<sub>3</sub> [232, 233]. At room temperature, it cannot burn downwards. Additional information on ammonia flammability and critical diameters for flame propagation in air is now available [234, 235].

Experiments investigating the flammability of hydrogen and ammonia as well as mixtures of these two fuels in air were performed in a 12.6-L combustion vessel at an initial pressure of 101 kPa (1 atm) and initial temperatures of up to 873 K (600 °C) [236]. Flammability maps based on the limiting fuel concentration as a function of the initial temperature for the various mixtures were constructed. The flammability limit data obtained for both hydrogen and ammonia by themselves agreed well with the data in the literature. The flammability limits for both air/hydrogen and air/ammonia were found to widen linearly with increased initial temperature. The lower flammability limits of air/hydrogen/ammonia mixtures at various initial temperatures were found to follow closely the Le Chatelier flammability limit mixing rule. We know that ammonia readily dissociates to hydrogen and nitrogen. The flammability limits of ammonia dissociation products mixed with undissociated ammonia and air were also measured at initial temperatures of 673, 773, and 873 K (400, 500, and 600 °C). For experiments at 773 and 873 K (500 and 600 °C), it was found that mixtures with a large fraction of dissociated ammonia auto-ignited upon injection into the test vessel. The range of mixtures that autoignited was larger at 873 K (600 °C) than at 773 K (500 °C). For mixtures with a large fraction of dissociated ammonia, autoignition of the mixture prevented the measurement of the fuel-rich flammability limit. The knowledge of flammability limits of hydrogen/air mixtures in air is valuable for the assessment of explosion hazards of hydrazine decomposition products from a gas generator or rocket engine operating in air at sea level, as is often done prior to moving to testing in a vacuum chamber.

As with hydrocarbons, an increase in either temperature or pressure tends to widen the flammable range of ammonia in air. The lower-limit flame temperature remains essentially constant with the increase in initial temperature.

Data on the flammable range of  $O_2/N_2/NH_3$  mixtures at higher than atmospheric pre-combustion pressures, as shown in Figure 40 show three curves, one for atmospheric pressure and room temperature and two for 688 kPa (100 psia) and room temperature and elevated temperature (422 K = 300 °F) [237]. The dotted line is the stoichiometric composition.

Partial decomposition of ammonia, such as in ammonia decomposition products used as protective atmosphere (“furnace gas”) in heat treatment furnaces, will form air/ammonia/hydrogen mixtures which have a wider range of flammability than undissociated ammonia.

## 8.2 The Flammable Range of Oxygen/Ammonia Mixtures

Other than using it as a fertilizer as is, one of the main industrial uses of ammonia is in the production of nitric acid which is then the main reactant in making fertilizers, explosives, and propellants. In the feed to the catalytic reactor, ammonia is mixed with oxygen or air, and the combustion may flash back into the mixing station and the feed system unless the pipes are protected by flashback arrestors in the form of stacks of narrow-mesh screens. The flammability limits of ammonia in oxygen are summarized in Table 41. In the 50-mm-diameter pipe at room temperature, the flammable range of ammonia in oxygen with upward propagation extended from 15.3 to 79 vol.-%.

Table 41 supplies several temperature-dependence data for oxygen/ammonia mixtures. Figure 41 gives the temperature dependence of the lower limit for higher temperatures approaching the ignition temperature [239].

**Table 41:** Flammability limits of ammonia in oxygen.

| Tube diameter<br>cm | Temperature<br>K | Direction of propagation |      |            |      |          |      |

**Figure 41:** Dependence of the lower limit of flammability of oxygen/ammonia mixtures on pre-combustion temperature and pressure. (Reproduced and modified from [239].)

### 8.2.1 Effect of Diluents on the Flammable Range of Air/Ammonia Mixtures

The inflammable limits of ammonia in air or oxygen-nitrogen mixtures, and particularly the effects of water vapor on these limits, were determined using a flame-quenching technique for determinations at atmospheric pressure and a dynamic bomb method at a pressure of ten atmospheres [240]. At atmospheric pressure, the flammability limits of ammonia in dry air were found to be 17.2 and 30.2 vol.-% ammonia, but these limits were found to narrow as the water vapor was increased until, at 10.8 vol.-%  $\text{H}_2\text{O}$  and 20.8 vol.-%  $\text{NH}_3$ , no flame could survive. With a dry oxygen-ammonia mixture, the lower limit was found to be 15.2 vol.-% ammonia. At ten atmospheres, the explosive limits of ammonia in dry air were found to be 16.9 and 28 vol.-%, and these limits were narrowed with addition of water vapor until, above 9 vol.-% water, no further explosion occurred. Nitrogen dilution in the flame gases of three rich  $\text{NH}_3/\text{O}_2/\text{N}_2$  flames had an effect on reaction kinetics [241].

### 8.2.2 Effect of Other Flammables on the Flammable Range of Air/Ammonia Mixtures

The Le Chatelier mixing rule can be applied to calculate the limits of flammability of mixtures of fuels with oxidizers such as oxygen or air. The predictive method gave only a rough approximation, deviating on either the safe side or the combustible side of the experimentally established limits when applying it to ammonia/fuel/air mixtures [242]. The flammable range of ammonia in oxygen or ammonia in air is widened substantially by the admixture of hydrogen [243] or methane [244]. Such mixtures may exist in the off-gas from ammonia production facilities. These flammable mixtures also once existed in the exhaust ducts from hydrazine-powered APUs on the STS Space Shuttle.

## 8.3 Autoignition Temperature of Air/Ammonia Combustion

The autoignition temperature of a stoichiometric mixture of ammonia with air is  $922\text{K} = 649^\circ\text{C}$ .

## 8.4 Electric-Spark Ignition Energy of Air/Ammonia Combustion

For the proposed use of ammonia as a fuel in internal combustion engines, the ignition energy required must be known. The ignition energy should also be known to evaluate the accidental ignition fire hazard in the vicinity of ammonia spills in air. Fortunately, the ignition energy, even for stoichiometric air/ammonia mixtures, is so high that it cannot be achieved by a typical electrostatic charge carried by a person that is not grounded. The ignition energy for air/ $\text{NH}_3$  mixtures is very high, at least 680 mJ for a stoichiometric mixture of air and  $\text{NH}_3$ . The hazard of accidental

ignition of air/ammonia mixtures by electrostatic charges is thus very low, much less than when working with hydrogen. However, air/ammonia/hydrogen mixtures such as those formed in the exhaust of hydrazine gas generators operating in air, are a potential explosion hazard.

The ignition energy required to ignite a stoichiometric GOX/ $\text{GNH}_3$  mixture is 680 mJ, much more than the 0.4 mJ required for igniting air/n-hexane vapor mixtures [237].

### 8.5 Fire Fighting of Air/Ammonia Fires

If for some odd reason a source of ammonia should have ignited, the fire is best fought with a strong water spray. Water spray will also be needed after the fire has been extinguished in order to absorb the unburnt ammonia and rinse the fire and spill site. Powder extinguishers are not suitable for ammonia fires because they are not as effective against unburnt ammonia as a strong water spray.

## 9 Properties of Ammonia Mixtures and Solutions

The unique properties of metal solutions in ammonia have attracted the interest of not only rocket propellant chemists, but scientists in general. There has even been an entire series of conferences devoted to free-electron and metal/ammonia solutions. The addition of lithium to ammonia has several purposes: it would make the solution hypergolic with nitric acid or dinitrogen tetroxide, increase the specific impulse, and lower the vapor pressure.

In 2014, searching the phrase “metal–ammonia solutions” in titles only in Google Scholar instantly produced 361 hits, and 51 of these were for lithium/ammonia solutions, obviously more than we can include in this book. See also [245, 246].

### 9.1 Lithium/Ammonia Solutions

In an early evaluation of ammonia, hydrazine, and hydrazine hydrate as rocket fuels, the potential use of lithium/ammonia solutions as fuels for WFNA or chlorine trifluoride was considered [247]. The vapor pressure of lithium/ammonia solutions is substantially lower than that of liquid ammonia.

### 9.1.1 Physical Properties of the Lithium/Ammonia System

Liquid ammonia has the unusual property that alkali metals dissolve in anhydrous ammonia and give up their free electron. The free electron imparts a deep blue color to the solution [248]. Physical chemical studies of dilute alkali metal/ammonia solutions indicated that the principal solution species are the ammoniated metal cation  $M^+$ , the ammoniated free electron  $e^-$ , the “monomer”  $M$ , the “dimer”  $M_2$ , and the “metal anion”  $M^-$ . The solution of alkali metals in liquid ammonia is reversible; if the ammonia is allowed to evaporate, alkali metals are left behind chemically unchanged in a highly reactive, finely dispersed form [249]. At higher concentrations, the surface of lithium solutions in ammonia assume a metallic copper-like sheen. Such solutions are potentially useful as rocket propellants, because the otherwise non-hypergolic liquid ammonia becomes hypergolic with a larger group of oxidizers and the specific impulse is increased due to the metal addition. Storage stability of these solutions may not be adequate for long-term missions [250].

In addition to theoretical interest in the nature of the solvated electron, these solutions also are unique reducing agents that have found applications in synthetic organic chemistry.

The physical properties of the lithium/ammonia system were investigated thoroughly by a group of investigators at the German Deutsche Versuchsanstalt für Luft- und Raumfahrt in Stuttgart [251].

In support of an investigation on the use of ammonia as a rocket propellant, the following properties of solutions of Li in  $NH_3$  have been studied [252]:

- the concentration of saturated solutions from 188 to 308 K (–85 to +35 °C);
- the variation of vapor pressure (up to 1500 mm Hg) with concentration and temperature;
- heats of vaporization, determined from vapor pressure versus temperature plots;
- densities from 203 to 278 K (–70 to +5 °C) and concentrations from 8.9 to 20.1 mol-% Li (the linear dependence of density on mol-% allowed extrapolation to higher and lower concentrations);
- corrosive action upon steel;
- variation of the rate of decomposition of saturated solutions with temperature.

#### Solubility of Lithium in Liquid Ammonia

The lithium concentration in a saturated solution decreases initially from about 21 mol-% at 188 K = –85 °C to 20.3 mol-% at 223 K = –50 °C, and then increases again to 21.5 mol-% at 308 K = +35 °C (Table 42).

#### Density of the Lithium/Ammonia System

The densities of lithium solutions in ammonia containing 8.9–20.1 mol-% Li at 203–278 K (–70 to +5 °C) are summarized in Table 43 and illustrated in Figure 42. While

**Table 42:** Solubility of lithium metal in liquid ammonia.

| Temperature |     | Saturation concentration of lithium |       |
|-------------|-----|-------------------------------------|-------|
| K           | °C  | Mass-%                              | Mol-% |
| 188         | -85 | 9.83                                | 21.10 |

Data source: [253].

**Figure 42:** Density isotherms of lithium/ammonia solutions as a function of lithium concentration. (Reproduced and modified from [251].)

most other slurries of metals in fuels will have higher densities than the fuel liquid, the opposite is the case with a solution of lithium in ammonia: the density of the solutions decreases with increasing lithium content.

### Compressibility and Velocity of Sound of the Lithium/Ammonia System

The velocity of 10-MHz sound waves in lithium/ammonia solutions has been determined for 23 different metal concentrations in the temperature range 89–240 K [254]. By combining these data with the available density data, the adiabatic compressibility of these solutions could be determined. The compressibility was found to be a monotonic increasing function of the concentration. An analysis of the sound velocity revealed a change in the dependence on concentration at a concentration of 5 mol-%. This is the concentration at which the metal–non-metal transition occurs, and was interpreted as evidence for a “structure” change accompanying the Mott transition.

The compressibility of concentrated metal/ammonia solutions has been calculated by assuming the solutions to be binary alloys of solvated metal ions (including the first solvation layer as part of the ion) and ammonia [255]. The isothermal compressibility  $\kappa_T$  was computed from the structure factor, which was computed from the Ascroft adaptation of a model for hard spheres. In the absence of adequate data on  $\kappa_T$ , the results of the computation were compared to data on the adiabatic compressibility  $\kappa_S$ .

### Vapor Pressure of the Lithium/Ammonia System

The addition of lithium metal decreases the vapor pressure of ammonia significantly (Figure 43). The vapor pressure reduction with all solutions containing more than 3 mol-% Li is higher than what one would expect in accordance with Raoult's law.

**Figure 43:** Vapor pressure isotherms of lithium/ammonia solutions. (Reproduced and modified from [251])

Earlier investigators had found the vapor pressure of lithium/ammonia solutions as listed in Table 44.

**Table 44:** Vapor pressure of lithium/ammonia solutions.

| Lithium,<br>mass-% | Mol ratio<br>NH <sub>3</sub> : Li | Temperature |       | Vapor pressure |      |
|--------------------|-----------------------------------|-------------|-------|----------------|------|
|                    |                                   | K           | °C    | mm Hg          | kPa  |
| 11.32              | 3.60                              | 273.1       | 0     | 34.0           | 4.53 |

Data source: [256]

Instead of vapor pressure, the boiling points of lithium/ammonia solutions at atmospheric pressure were measured as a function of lithium concentration, as summarized in Table 45. See also [257].

**Table 45:** Boiling points of lithium/ammonia solutions.

| Lithium concentration |        | Boiling point |       |
|-----------------------|--------|---------------|-------|
| Atom-%                | Mass-% | K             | °C    |
| 2.31                  | 0.95   | 240.0         | −33.1 |

### Optical Properties of Lithium/Ammonia Solutions

Lithium dissolved in ammonia gives the solution a deep blue color. The absorption spectrum of lithium solutions in ammonia has a maximum of absorption at 6650–6700 cm<sup>−1</sup> (1492 nm). The spectra of all alkali metal solutions in ammonia are similar [259, 260].

### Thermal Conductivity of Lithium/Ammonia Solutions

Adding alkali metals to ammonia improves the thermal conductivity of the solution substantially, approaching the thermal conductivity of molten alkali metals.

The thermal conductivity of solutions of lithium, sodium, or potassium in liquid ammonia has been measured as a function of temperature and concentration [261]. The conductivity showed a strong dependence on concentration and rose with increasing concentration to values of 30–60 mW cm<sup>-1</sup> K<sup>-1</sup> at saturation. Pure ammonia has a conductivity of only 5 mW cm<sup>-1</sup> K<sup>-1</sup>. Two modes of heat transport, molecular and electronic, may have to be invoked to interpret the data. The molecular term followed a semi-empirical equation often used for insulating liquids. The electronic heat conductivity obeyed a Wiedemann–Franz law often used for solid metals, with a Lorenz number about 75% of the free-electron value.

### Electrical Conductivity of Lithium/Ammonia Solutions

With the solvated electron acting as a very fast carrier of electrical currents, it is of mostly theoretical interest to measure the electrical conductivity of lithium/ammonia solutions [262]. Measurements of electrical conductivities of Li/NH<sub>3</sub> and Cs/NH<sub>3</sub> solutions showed that temperature coefficients of conductivities became negative at higher concentrations and temperatures [238]. The electrical conductivity of solutions of lithium in liquid ammonia have been measured as a function of composition and temperature [263]. The transition from the semiconducting to the metallic state takes place in the intermediate concentration range, around 4.5 mol-% lithium.

Observations of the transport properties of several metallic metal/ammonia solutions indicated an electrical conductivity that rose sharply with increasing concentration of the metallic component [264]. It was attempted to explain this behavior by a model of independent scatterers, in this case dipolar scattering from ammonia molecules and scattering from solvated metal ion complexes. Numerical estimates of the cross-sections involved the details of the reduction of the corresponding potentials by the presence of electrons and dipoles. This required dielectric functions for a system of point dipoles and electrons.

### Thermodynamic Properties of the Lithium/Ammonia System

The heats of solution of Li, Na, and K metal in anhydrous ammonia at 298 K (25 °C) have been measured at concentrations down to 0.005 M [265, 266]. The solution of lithium in liquid ammonia is exothermic with 33.5 kJ/mol Li (8 kcal/mol). Dilution is endothermic, and the heat of dilution is greater in the presence of an added Na<sup>+</sup> ion.

### 9.1.2 Chemical Properties of the Lithium/Ammonia System

Ideally, ammonia should only serve as an inert solvent for the alkali metals, and all formation of metal amides is highly undesirable if the solutions are to be used as rocket propellants. However, alkali metals do slowly react with anhydrous ammonia even at room temperature [267].

The self-decomposition reaction of concentrated solutions of lithium in ammonia at atmospheric pressure was studied at various temperatures in polyethylene and in glass containers by observing the change in weight of the solution [268]. The reaction followed a first-order rate law and was apparently heterogeneous. An unusually large, negative value for the activation entropy and a relatively low activation energy were found for this reaction. Possible explanations for these results included the concepts that the solvated electron was involved in the decomposition reaction and that electron transfer occurred by a tunneling mechanism.

Isotopic substitution in neutron diffraction has been used to study the structure of saturated solutions of lithium and potassium in ammonia [269, 270]. Isotopic substitution of  $^*N$  by  $^{15}N$ , combined with difference analysis, showed that  $K^+$  acts as a “structure breaking” ion while  $Li^+$  acts as a “structure making” ion. It was found that lithium is tetrahedrally coordinated by ammonia molecules, at both 230 and 100 K. Potassium, on the other hand, is octahedrally coordinated at 160 K. A saturated metallic solution of lithium in ammonia contained 21 mol-% metal.

## 9.2 Ammonia/Hydrazine Mixtures

Ammonia and hydrazine are both hydronitrogens. Both are being used or have been used as rocket fuels. As close relatives of the same family of chemical compounds, they are totally miscible with each other over the entire range of compositions. Hydrazine can be added to ammonia to improve its hypergolic ignition with nitric acid or dinitrogen tetroxide as the oxidizer. Ammonia can be added to hydrazine to lower its freezing point and reduce its autodecomposition tendencies.

Mixtures of ammonia with hydrazine have unique features dominated by strong hydrogen bonding between the two (or several) molecules, although the interaction is not as strong as between ammonia and water or between hydrazine and water. Adding hydrazine to ammonia will lower the vapor pressure of ammonia and make it easier to handle. Adding ammonia to hydrazine will lower the exhaust temperature when hydrazine is used as a monopropellant, and will also lower the freezing point, thus requiring less heater power in a satellite to keep the hydrazine in the propellant tank from freezing. However, in a monopropellant application, adding ammonia to hydrazine will lengthen the ignition delay and shorten the catalyst life when many startups are needed. Ammonia/hydrazine mixtures have some attractive features but have not been used in flight applications up to now [271].

### 9.2.1 Physical Properties of the Ammonia/Hydrazine System

The physical properties of ammonia/hydrazine mixtures were measured thoroughly over a wide range of ratios and temperatures. These mixtures are of interest as hypergolic fuels with WFNA, RFNA, or NTO because they would be more hypergolic than ammonia alone and are more economical fuels and better regenerative coolants than pure hydrazine. They are also of interest as monopropellants when the temperature of hot gases from decomposing 100% hydrazine is too hot for turbine blades or expulsion bladders in gas generator applications.

Ammonia/hydrazine mixtures should be discussed only at one location in this book, either under ammonia or under hydrazine. It has been decided to discuss them at the first possible location, which is here under ammonia. A short reference in *Encyclopedia of Liquid Fuels*, chapter “Hydrazine,” will direct readers back to this location.

#### 9.2.1.1 Freezing Point of the Ammonia/Hydrazine System

The freezing point diagram of the binary hydrazine/ammonia system is illustrated in Figure 44. The lowest melting composition is a eutectic with 92.64 mol-% ammonia melting at approximately 193 K [272, 273].

**Figure 44:** Freezing point diagram for the binary  $NH_3/N_2H_4$  system. (Reprinted and modified from [272], with permission from ©1957 American Chemical Society; permission conveyed through RightsLink.)

### 9.2.1.2 Freezing Point of the Ammonia/Hydrazine/Water System

The freezing points of the ternary ammonia/hydrazine/water system are illustrated in Figure 45. There is a range where the liquid does not crystallize, but turns into a viscous, glassy substance. It is not possible to determine freezing points in this area [22].

**Figure 45:** Melting point of the ternary  $\text{NH}_3$ - $\text{N}_2\text{H}_4$ - $\text{H}_2\text{O}$  system. (Reproduced and modified from [22].)

The ternary  $\text{N}_2\text{H}_4/\text{NH}_3/\text{H}_2\text{O}$  system has been investigated in the temperature range 183–233 K [274]. The isotherms at 233, 221, 190, and 182 K have been established over the entire range of compositions. Seven solid phases were identified:  $\text{N}_2\text{H}_4$ ,  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}$ ,  $\text{N}_2\text{H}_4 \cdot 4\text{H}_2\text{O}$ ,  $\text{NH}_3$ ,  $2\text{NH}_3 \cdot \text{H}_2\text{O}$ ,  $\text{NH}_3 \cdot \text{H}_2\text{O}$ , and  $\text{H}_2\text{O}$ . Below 193 K, anhydrous hydrazine precipitated from solutions starting out with hydrazine hydrate and ammonia. This is a possible method to make anhydrous hydrazine from hydrazine hydrate.

### 9.2.2 Density of Ammonia/Hydrazine Mixtures

The density of hydrazine/ammonia mixtures at  $229 \pm 1$  K is summarized in Table 46 and can be represented by

$$\rho\left(\frac{\text{g}}{\text{cm}^3}\right) = 0.6983 + 0.002837X$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $X$  is the hydrazine concentration in mass-%. The density at 293 K can be calculated from

$$\rho = 1.014557 - 5.5688 \times 10^{-3}X + 1.7735 \times 10^{-5}X^2 - 2.37 \times 10^{-8}X^3$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $X$  is the ammonia concentration in mass-%. Density data for ammonia/hydrazine mixtures are listed in Table 46.

**Table 46:** Density of ammonia/hydrazine mixtures.

| Ammonia | Hydrazine <sup>a</sup> | Temperature |       | Density                | References |
|---------|------------------------|-------------|-------|------------------------|------------|
| Mass-%  | Mass-%                 | K           | °C    | $\text{g}/\text{cm}^3$ |            |
| 100     | 0                      | 228.1       | -45   | 0.6986                 | [275]      |
| 92.6    | 7.4                    | 227.6       | -45.5 | 0.7200                 | [275]      |
| 89.1    | 10.9                   | 226.6       | -46.5 | 0.7280                 | [275]      |
| 87.0    | 13.0                   | 226.1       | -46.0 | 0.7346                 | [275]      |
| 84.1    | 15.9                   | 229.1       | -44.0 | 0.7442                 | [275]      |
| 77.8    | 22.2                   | 229.6       | -43.5 | 0.7596                 | [275]      |
| 73.5    | 26.5                   | 230.1       | -43.0 | 0.7749                 | [275]      |
| 40.1    | 59.9 <sup>a</sup>      | 235.2       | -37.9 | 0.9036                 | [276]      |
| 40.1    | 59.9 <sup>a</sup>      | 250.1       | -23   | 0.8877                 | [276]      |
| 40.1    | 59.9 <sup>a</sup>      | 265.3       | -7.8  | 0.8724                 | [276]      |
| 40.1    | 59.9 <sup>a</sup>      | 279.1       | 6.0   | 0.8562                 | [276]      |
| 40.1    | 59.9 <sup>a</sup>      | 292.9       | 19.8  | 0.8416                 | [276]      |
| 40.1    | 59.9 <sup>a</sup>      | 306.1       | 33    | 0.8284                 | [276]      |

<sup>a</sup> Hydrazine used for this test was not pure. It contained 4.5% water to start with.

The density of ternary hydrazine/ammonia/water mixtures increases fairly uniformly from the ammonia corner of the ternary diagram to the hydrazine-water side of the triangle (Figure 46).

**Figure 46:** Density of ternary hydrazine/ammonia/water mixtures at 298 K (77 °F). (Reproduced and modified from [163].)

### 9.2.2.1 Vapor/Liquid-Phase Composition of Ammonia/Hydrazine Mixtures

The liquid/vapor phase equilibrium compositions in the ammonia/hydrazine system have been extensively investigated over the course of several decades, but no applications of such mixtures as monopropellants have materialized [277–283].

Sometimes ammonia/hydrazine mixtures are obtained during the preparation of anhydrous hydrazine in the laboratory and have to be separated. This is one of the reasons why these mixtures are discussed in a little more detail here. The vapor-phase composition of  $\text{NH}_3/\text{N}_2\text{H}_4$  mixtures must be known in order to decide if complete separation by fractional distillation can be achieved. Unlike the  $\text{N}_2\text{H}_4/\text{H}_2\text{O}$  system, no azeotropes are formed in the  $\text{NH}_3/\text{N}_2\text{H}_4$  system, and separation is easy because of the disparate boiling points.

The earliest vapor pressure measurements were those listed in Table 47. The mixtures chosen were those that were in equilibrium with solid hydrazine at the temperature stated. The author also has an interesting method to represent vapor pressure data of binary systems and their dependence on temperature in the form of an isomet-

**Table 47:** Vapor pressure of equilibrium-melting ammonia/hydrazine mixtures.

| Temperature<br>K | Vapor pressure |       | Hydrazine<br>Mass-% |
|------------------|----------------|-------|---------------------|
|                  | kPa            | mm Hg |                     |
| 193              | 5.31           | 40    | 13                  |

| 263              | 82.4           | 620   | 87.6                |
| 268              | 62.5           | 470   | 92.6                |
| 273              | 23.25          | 175   | 98.0                |
| 274              | 13.95          | 105   | 98.6                |

Data source: [273]

ric view of a 3-D vapor pressure surface (instead of a vapor pressure curve in an X-Y graph).

Total vapor pressure, liquid-phase composition, and vapor-phase composition of ammonia/hydrazine mixtures were measured for molecular fractions of  $x_{\text{NH}_3}$  from 0.2 to 0.95 and temperatures from 361.6 to 398 K (from 88.5 to 124.9 °C) [279]. Data could not be obtained with liquid compositions greater than 80%  $\text{N}_2\text{H}_4$  because of considerable hydrazine decomposition in the steel autoclave used. Because of relatively small concentrations of hydrazine in the gas phase, it was assumed that the pressure–fugacity relationships for ammonia alone could be applied to the gas mixtures. The values reported for the total experimental vapor fugacity were calculated from the measured total vapor pressure by calculating a virial coefficient called  $B_{\text{mix}}$ :

$$B_{\text{mix}} = N_1^2 + 2N_1N_2 \frac{B_1 + B_2}{2} + N_2^2 B_2$$

where  $N_1$  and  $N_2$  are the mol fractions of the two compounds. Since  $B_{\text{mix}}$  and  $B(\text{NH}_3)$  are known,  $B(\text{N}_2\text{H}_4)$  was calculated from the above equation and an EOS

$$pV = nRT + Bp$$

The virial coefficients for hydrazine thus obtained are listed in Table 48.

Activities and activity coefficients for hydrazine in dilute hydrazine solutions in liquid ammonia could not be calculated because the vapor composition of dilute hydrazine solutions in ammonia could not be measured. Partial fugacities of hydrazine for solutions containing low hydrazine concentrations were not in accordance with Henry's law, although the partial fugacities of ammonia in these solutions were in ac-

**Table 48:** Virial coefficients for hydrazine in ammonia/hydrazine mixtures.

| Temperature, K | Virial coefficient, L/mol |
|----------------|---------------------------|
| 363            | 2.14                      |
| 368            | 3.49                      |
| 373            | 3.58                      |
| 383            | 4.32                      |
| 393            | 4.20                      |

Data source: [279]

cordance with Raoult's law. The activity coefficients for ammonia indicated that ammonia is behaving in accordance with Raoult's law up to 15 mol%  $\text{N}_2\text{H}_4$ . Accordingly, Henry's law should be obeyed in the same range. This trend is caused by association of hydrazine molecules in solution. At higher  $\text{N}_2\text{H}_4$  concentrations, the association in the liquid phase becomes more pronounced.

Since hydrazine is not associated in the vapor phase, the fugacity of hydrazine is directly proportional to the concentration of the monomer in the solution. The measurements by Drago and Sisler were eventually extended over the entire range of concentrations and also to lower temperatures (298 and 373 K) [281, 282].

Previous literature contained only hydrazine/ammonia vapor pressure data for the range from 361 to 398 K, but no data on the range of more practical interest were available prior to 1967. Additional measurement results obtained on seven mixtures with ammonia mol fractions from 0.1547 to 0.9162 can be represented by the following curve-fit equation [280]:

$$\log p_v = A + BT$$

where  $p$  is the vapor pressure in MPa and  $T$  is the absolute temperature in K. The coefficients  $A$  and  $B$  for this equation are listed in Table 49.

Vapor pressures of a 63.8% hydrazine (only 96.5% pure hydrazine was available at the time)/36.2% ammonia blend are summarized in Table 50.

**Table 49:** Vapor pressure coefficients for ammonia/hydrazine mixtures.

| Mol fraction $\text{NH}_3$ | A       | B         |
|----------------------------|---------|-----------|
| 0.1547                     | 3.49852 | -1296.960 |
| 0.3415                     | 3.62369 | -1198.108 |

| 70.0        | 343.1 | 1873           | 14050 |

Data source: [276]

These data can be expressed by

$$\log p = 7.413 - \frac{1120}{T}$$

where  $p$  is the pressure in mm Hg and  $T$  is the temperature in K. The solubility of ammonia in hydrazine was determined at 298, 303, 313, 323, 333, and 343 K [278]. When plotting the solubility against partial pressures of ammonia for the various temperatures, the otherwise straight lines showed a slight curvature as the pressures approached atmospheric pressure, indicating a slight deviation from Henry's law. At higher temperatures, this deviation became smaller until, at 343 K, the solubility almost obeyed Henry's law over the entire pressure range studied (4–95 kPa).

The solubility of ammonia in hydrazine could also be expressed in terms of the Bunsen absorption coefficient  $\alpha$  and the Ostwald coefficient for solubility  $L$ . The Bunsen coefficient is defined as the volume of gas reduced to 273 K and 1 atm (101 kPa = 14.686 psia), dissolved by unit volume of solvent at the temperature of the experiment at a partial pressure of the gas of 1 atm (101 kPa = 14.686 psia). The Ostwald coefficient of solubility is defined as the volume of gas, measured under the temperature and pressure at which the gas dissolves, taken up by unit volume of the liquid. It is related to the Bunsen coefficient by  $L = \alpha/273$ . Table 51 gives a summary of these two

**Table 51:** Solubility coefficients of ammonia in hydrazine.

| Temperature |     | Bunsen coefficient | Ostwald coefficient |
|-------------|-----|--------------------|---------------------|
| K           | °F  | $\alpha$           | $L$                 |
| 298         | 77  | 57.71              | 62.99               |
| 303         | 86  | 49.56              | —                   |
| 313         | 104 | 37.44              | —                   |
| 323         | 122 | 27.78              | —                   |
| 333         | 140 | 20.92              | 25.52               |
| 343         | 158 | 16.49              | 20.72               |

Data source: [280]

solubility coefficients. If one plots  $\log L$  versus  $1/T$  (reciprocal absolute temperature), one obtains a straight-line relationship. The heat of solution of ammonia in hydrazine can be derived from the slope of this curve. The straight line indicates that the heat of solution is not a function of the temperature in the range studied.

### 9.2.2.2 Vapor-Phase Composition of Monomethylhydrazine (MMH)/Ammonia and UDMH/Ammonia Mixtures

Deviations from Henry's law constants were listed for ammonia both above and in liquid hydrazine, MMH, and UDMH. These were eventually used to calculate the heat of solution of ammonia in these liquids. At 298 K and 1.2207 atm total pressure, the equilibrium mol fraction ammonia in the liquid is 0.0975 and Henry's constant  $K = X/f$  is 0.0808. Surprisingly, ammonia is less soluble in hydrazine than in UDMH or MMH. The relative solubility in the two methylhydrazines is as expected, with ammonia being more soluble in MMH than UDMH.

### 9.2.2.3 Viscosity of Ammonia/Hydrazine Mixtures

The viscosity of hydrazine/ammonia mixtures has been determined at six different temperatures over the entire range of compositions [280]. The data illustrated in Figure 47 were obtained using a falling sphere viscometer modified for operation at high fluid pressures.

**Figure 47:** Viscosity of ammonia/hydrazine mixtures. (Reproduced and modified from [280].)

### 9.2.2.4 Viscosity of Ammonia/Hydrazine/Water Solutions

Ternary ammonia/hydrazine/water solutions have been evaluated as monopropellants and as fuels for automobiles with reciprocating internal combustion engines. Viscosities of ternary ammonia/hydrazine/water solutions are illustrated in Figure 48.

**Figure 48:** Viscosity of ammonia/hydrazine/water ternary fuel blends. (Reproduced and modified from [163])

### 9.2.3 Chemical Properties of Ammonia/Hydrazine Mixtures

Ammonia/hydrazine mixtures can be analyzed by low-temperature thermogravimetry [275]. Gas mixtures of ammonia and hydrazine at low pressures were analyzed by first completely decomposing the hydronitrogens in an arc discharge and then analyzing the nitrogen/hydrogen mixture by mass spectrometry [284].

### 9.3 Other Fuel Mixtures with Ammonia

Because ammonia is a very cheap fuel with a chemical composition similar to that of hydrazine, a very desirable (but quite expensive) rocket propellant, there have been attempts to improve its hypergolic ignition with nitric acid or  $N_2O_4$  oxidizers by adding hypergolizing additives.

Other additives were aimed at improving the specific impulse, regardless of their ability to aid hypergolic ignition. One of the most promising additives is acetylene (ethyne).

#### 9.3.1 Ammonia/Acetylene Fuel Mixtures

In 2012, it was reported that the Russian rocket engine manufacturer Energomash had started development of a new rocket engine which could vastly reduce the cost of rocket launches and avoid the need to produce cryogenic hydrogen for fuel. Instead, the rocket was described as using “a completely novel fuel mixture of acetylene and ammonia (*atsetam*).” Officials expected to launch the new rocket in 2017 or 2018 “dependent on funding.” However, when the Internet and other sources were checked eight years later, there had been no additional announcements on eventual progress made in this development. The new rocket was expected to be around 30% more efficient than existing designs, working on a fuel mixture of acetylene and ammonia which is 20 times cheaper than hydrogen; a kilogram of hydrogen costs about 2000 rubles (\$67) and a kilo of *atsetam* can be made for 100 rubles (\$3.35), Energomash’s Director of Innovative Technology, Anatoly Likhvantsev, told the *Izvestiya* newspaper. The new *atsetam* engine will be assembled on the basis of the RD-161 oxygen and kerosene engine which has a successful history in hundreds of launches. Images of the engine shown with a news release reminds one of the bulbous design of the A-4 (V2) engine used in Germany in 1943.

The exact parameters were to be determined during tests which began in 2012 and were supposed to last for about three years. Once the optimal ratio of acetylene and ammonia is found (in which fuel will be sufficiently powerful without exploding too easily), the designers plan to specify the parameters of the engine. According to preliminary calculations, the *atsetam* engine will not require major structural changes to be made to existing rocket motors since the physical properties of *atsetam* do not differ much from those of kerosene.

Ammonia and acetylene are miscible over the entire range of compositions. Ammonia is a protonophilic compound of average basicity, while acetylene is a proton-donor compound with a weak acid character. The hydrogen forming the hydrogen bond between the two molecules comes from the acetylene, not from the ammonia, and extends from the acetylene molecule to the free-electron pair on the nitrogen atom. The spectral analysis revealed that acetylene binds to ammonia through a  $C-H\cdots N$  weak hydrogen bond to form a  $C_{3v}$  symmetric top, consistent with

the previous microwave and IR spectroscopic studies at 3  $\mu\text{m}$ . Acetylene/ammonia system shows small negative deviations from Raoult's law. Such deviations, as foreseen, increase as the temperature decreases and have to be ascribed to ammonia/acetylene interactions of both the chemical and physical type.

Prior to considering them as a rocket fuel, ammonia/acetylene mixtures were used as a solvent for acetylene in organic synthesis reactions where the use of undiluted acetylene might constitute an undue explosion hazard [285].

The possibility of acid–base interactions between acetylene and ammonia lead to the formation of a complex by hydrogen bonding according to the equilibrium equation

for which an equilibrium constant in the temperature range 323–423 K (50–150 °C) has been calculated.

Vapor–liquid equilibrium data of the acetylene/ammonia system for seven isotherms in the ranges 213–298 K (–60 to 25 °C) and 0.1–3.24 MPa (1–32 atm) were measured and interpreted according to the thermodynamics of associated systems [286]. It was shown that thermodynamic consistency could be observed by assuming a bimolecular complex formation between acetylene and ammonia. Equilibrium constants for this complex in the liquid phase have been derived and related to the corresponding gas phase values known from the literature. Figure 49 shows the vapor pressure isotherms in the ammonia/acetylene system in the 248–213 K (–25 to –60 °C) range. Vetere, Cojutti, and Scaramucci [286] include additional charts for higher temperature ranges. The curvature indicates a deviation from Raoult's law often observed with the formation of compounds or close associates. The acetylene/ammonia system shows small negative deviations from Raoult's law. Such deviations increase as the temperature decreases.

The Vetere, Cojutti, and Scaramucci publication also contains data on the equilibrium constant of the associate–product formation between ammonia and acetylene as a function of temperature, also in comparison to the dimerization of ammonia in the gas phase [286]. The equilibrium constant for  $\text{NH}_3\text{—C}_2\text{H}_2$  adduct formation is bigger than the equilibrium constant for ammonia dimerization. The enthalpy of reaction of adduct formation is  $\Delta H_0 = -9247 \pm 1255 \text{ J/mol}$  ( $-2210 \pm 300 \text{ cal/mol}$ ).

Volumetric data for gaseous ammonia/acetylene mixtures have been analyzed to obtain second virial coefficients as a function of temperature and composition [287]. From the pure-component virial coefficients of ammonia and acetylene, EOS parameters were obtained and used to calculate the physical contributions to the second cross-virial coefficients. The difference between the experimental coefficient and that calculated from the physical contribution can be attributed to chemical interaction, or complex formation, between the two molecules. Chemical equilibrium constants indicated a very weak hydrogen bond formation between the nitrogen atom in the ammonia and the hydrogen atom in acetylene. The concave curvature of the lines in

**Figure 49:** Vapor pressure isotherms of ammonia-acetylene mixtures. (Reprinted and modified from [286], with permission from ©1975 Elsevier; permission conveyed through RightsLink.)

a graph of second virial coefficients of ammonia/acetylene mixtures indicated strong compound formation in the middle of the mixture range, in particular at low temperatures. See also [288–291].

It was shown that thermodynamic consistency could be observed by assuming the formation of a bimolecular complex between acetylene and ammonia. Equilibrium constants for this complex in the liquid phase have been derived and related to the corresponding gas phase values known from the literature.

Interestingly, from a standpoint of theoretical chemistry, ammonia and acetylene form an adduct where the two molecules are linked together by hydrogen bonding [292]. At low temperatures, the two gases form co-crystals. Ammonia/acetylene fuel mixtures had been burned with oxygen in the laboratory, but no rocket engine tests were documented prior to the Russian studies.

The theoretical rocket performance of LOX/NH<sub>3</sub>-C<sub>2</sub>H<sub>2</sub> combinations was calculated [293]. We are looking forward to reports that this new propellant combination has actually flown.

### 9.3.2 Hypergolization of Ammonia by the Addition of Alkali- or Earth Alkaline Metals

Dilute solutions of alkali metals in ammonia electrons are localized in cavities in the solvent, and their thermodynamic and transport properties are very similar to those of dilute solutions of strong electrolytes. At higher concentrations, the properties deviate markedly from those of electrolyte solutions and approach those of a liquid metal.

Experiments at NASA have shown that even very small amounts of lithium or calcium dissolved in ammonia will hypergolize its reaction with  $\text{N}_2\text{O}_4$  (NTO) or  $\text{N}_2\text{O}_3/\text{N}_2\text{O}_4$  (MON) [294, 295]. Because the solutions are not storable, in many cases, it was sufficient to allow the propellant to flow over a chunk of lithium or calcium metal on its way into the rocket engine. This brief contact dissolved sufficient metal to make the ammonia hypergolic. The lithium or calcium content of the liquid ammonia will not only facilitate ignition, but also assures more stable combustion and avoids combustion pressure instabilities even after the engine has started. By adequately sizing the geometry of the metal grain in the cartridge (similar to a hybrid grain), the metal concentration in the ammonia leaving the cartridge can be kept fairly constant even as the grain surface recedes. Ammonia used for this purpose must be completely water-free because metal hydroxides are insoluble and will clog the injector orifices.

Based on the NASA tests, lithium is preferable to calcium for the hypergolization of ammonia. As far as performance is concerned, the type of metal makes little difference because only a small percentage of metal is dissolved in the fuel.

Other organizations have patented the application of metalized ammonia as a rocket propellant in combination with WFNA, RFNA, mixed acid, or hydrogen peroxide, using an alkaline earth metal (calcium or strontium) in concentrations ranging from 0.01 mass-% all the way to saturated solutions [296].

Metallic calcium dissolves in liquid ammonia, similar to the more widely investigated lithium/ammonia solutions. The viscosity of concentrated solutions of calcium in liquid ammonia was determined with solutions containing 3.4–8.9 mol-% calcium at temperatures from 233 to 213 K [297].

### 9.3.3 Hypergolization of Ammonia by Addition of Metal Hydrides

Some metal hydrides will react with ammonia forming hydrogen and metal amides, but some complex hydrides such as lithium borohydride instead will form ammoniates, some of which are solids at room temperatures. Lithium borohydride  $\text{LiBH}_4$  forms ammoniates that contain one, two or three molecules of ammonia in the solvate sphere, melting at 325, 284 or 312 K (52, 11 or 30 °C), respectively. Solutions of these ammoniates in liquid ammonia lower the vapor pressure of ammonia substantially, such that the vapor pressure of a solution containing >30%  $\text{LiBH}_4$  is <1 bar. Such solutions are hypergolic with either WFNA or  $\text{H}_2\text{O}_2$  [108].

### 9.3.4 Hypergolization of Ammonia by Addition of Hypergolic Fuels

In addition to lithium, a number of other additives have been tested to make ammonia hypergolic with common hypergolic oxidizers. Of all the mixtures, the mixture of ammonia with hydrazine has received the most attention and has been tested in several rocket engines with different oxidizers. Hydrazine and ammonia are chemically similar and are miscible over the entire range of compositions. Hydrazine/ammonia mixtures will be discussed in more detail in the hydrazine chapter (see volume 2, chapter “Hydrazine”).

Ammonia is completely miscible with UDMH, MMH, triethylamine, and methylamines. At least 25% UDMH is required to make ammonia hypergolic with WFNA.

### 9.3.5 Ammonia/Alkanol Fuel Mixtures

Ammonia and methanol are miscible over the entire range of mixture ratios. An ammonia/methanol mixture would be a very economical rocket fuel, with good regenerative cooling properties in bipropellant engines. The addition of methanol lowers the vapor pressure of ammonia [298], similar to the effect of adding water. The heat transfer properties of ammonia/methanol mixtures have been studied as an example of molecular simulation computational chemistry models [299]. Ammonia can also be absorbed in ethanol.

## 10 Applications of Ammonia as an Energy Carrier

Many applications of chemicals that were first developed for the space program later found applications in other sectors of the industry. The alternative energy and alternative energy carrier programs benefit from the information that is now available on energy sources and energy carriers and derived from the space program. Some of the prospective uses of ammonia are discussed here.

### 10.1 Ammonia for Internal Combustion Engines

There have been many attempts to use ammonia as a fuel in reciprocating internal combustion engines. Ammonia/air mixtures do not ignite very readily, at least not as readily as gasoline/air mixtures. Thus, many additives have been evaluated to improve the ignition characteristics of ammonia in combustion engines. These include hydrazine, alkylhydrazines, 2-hydroxyethylhydrazine, boranes, alkylboranes, and borane–amine complexes [300]. There is an organization that promotes the use of ammonia as automotive fuel, the  $\text{NH}_3$  Fuel Association [301]. The advantage of ammonia as an automotive fuel would be that it does not emit climate-changing carbon dioxide when it is burned. A ternary fuel, designated TF-1, consisting of

64% hydrazine, 10% ammonia, and 26% water, has been tested in a stationary internal combustion engine and proposed as an environmentally friendly (i.e. no CO<sub>2</sub> emissions) alternative to gasoline [2].

## 10.2 Ammonia as a Storage Medium for Excess Energy

Developers around the world are looking at using ammonia as a form of energy storage, essentially turning an ammonia storage tank into a very large chemical energy storage battery [302].

In the UK, Siemens is building an “all-electric ammonia synthesis and energy storage system.” [303]. In the Netherlands, Nuon’s is studying the feasibility of power to ammonia conversion “to convert high amounts of excess renewable power into ammonia, store it and burn it when renewable power supply is insufficient.” The design of installations like this may benefit from the experience gained with ammonia as a rocket propellant.

There are several studies on the design and performance of a grid-scale ammonia energy storage system. Ammonia is being examined as an energy storage system for integrating intermittent renewables on the utility scale [304].

# Aromatic Amines

## Introduction

*Encyclopedia of Liquid Fuels* contains three chapters on amines, the current chapter on “Aromatic Amines,” a chapter on “Aliphatic Amines,” and a very large chapter on “Heterocyclic and Heterocycloaliphatic Amines.” Amines are used as rocket fuels and as raw materials for the synthesis of other fuels and energetic compounds. A different type of amine are the nitramines described in the chapter “Nitramines.”

## 1 Aromatic Amines

Aromatic amines, also called arylamines, contain a benzene ring with one or more amino and potentially other groups attached to the ring. The main member of this family of rocket fuels is aniline, aminobenzene, a primary amine, which was used as a rocket fuel either by itself or in a mixture with furfuryl alcohol in the early days of liquid rocket experimentation. Other compounds of interest for rocket propellant formulations are stabilizers for double-base solid propellants based on a secondary amine, diphenylamine. Most organic chemistry books and many encyclopedias, such as Ullmann's [1] or Kirk-Othmer's [2], contain chapters on aromatic amines.

### 1.1 Physical Properties of Aromatic Amines

An excellent 69-page summary of physical properties of primary arylamines was published as part of the National Bureau of Standards, National Standard Reference Data Series (NBS NSRDS) [3]. This summary includes data on thermodynamic and thermophysical properties of eight primary amines including benzeneamine and 2-, 3-, and 4-methylbenzeneamine, and recommended values are given for the normal boiling point, freezing point, and triple point temperatures, critical constants, thermodynamic properties in the solid and liquid phases, vapor pressure, enthalpy of vaporization, density, second virial coefficients, and enthalpy of combustion. Ideal gas thermodynamic properties were calculated by statistical mechanical methods. The boiling points were taken from a least-squares fit of the Cox equation (Table 1).

**Table 1:** Selected freezing, normal boiling, and critical temperatures of primary aromatic amines.

| Compound                  | Freezing point,<br>K        | Boiling point,<br>K | Critical point<br>temperature,<br>K | Critical point<br>pressure,<br>MPa | Critical<br>point<br>volume,<br>cm <sup>3</sup> /mol |
|---------------------------|-----------------------------|---------------------|-------------------------------------|------------------------------------|------------------------------------------------------|
| Benzeneamine<br>(aniline) | 267.133 ± 0.01 <sup>a</sup> | 457.32 ± 0.08       | 699 ± 2                             | 4.89 ± 0.12                        | 280 ± 14                                             |
| 2-Methyl-<br>benzeneamine | 256.8 ± 0.1                 | 473.49 ± 0.04       | 707 ± 2                             | 4.37 ± 0.12                        | 333 ± 17                                             |
| 3-Methyl-<br>benzeneamine | 241.9 ± 0.1                 | 476.52 ± 0.04       | 707 ± 2                             | 4.28 ± 0.12                        | 333 ± 17                                             |
| 4-Methyl-<br>benzeneamine | 316.9 ± 0.1                 | 473.57 ± 0.08       | 706 ± 2                             | 4.58 ± 0.14                        | 340 ± 17                                             |

## 2 Aniline

Aniline, also known as benzeneamine, phenylamine, aminobenzene, C<sub>6</sub>H<sub>5</sub>NH<sub>2</sub>, CAS RN [62-53-3], is readily available and was used as a rocket fuel in the early years of rocketry but is no longer used for this purpose. It reacts hypergolically with all types of nitric acids, including white fuming nitric acid (WFNA), inhibited red fuming nitric acid (IRFNA), and mixed acid, but requires some additives to shorten the ignition delay.

The use of aniline as a rocket propellant is now mostly only of historical interest. Aniline played a role in the early days of liquid rocket experimentation and enabled the United States to achieve a few significant milestones, such as the first two-stage sounding rocket to reach a record altitude of 400 km. This milestone was achieved by the second stage of the V2/WAC Corporal combination (Operation Bumper) at White Sands Launch Complex 33 on 24 February 1949. Historically, a portion of the literature on amines as rocket propellants has always dealt with aniline, the simplest member of the family of aromatic amines, but this may no longer be necessary in the age of hydrazine fuels. We are listing aniline and its methyl derivatives here only as chemicals of historical interest.

Aniline is the simplest of the primary aromatic amines [4]. Aromatic amines can be produced by reduction of the corresponding nitro compounds, ammonolysis of an aromatic halide or phenol, and direct amination of the aromatic ring [4, 5]. At present, the catalytic reduction of nitrobenzene is the predominant process for manufacture of aniline. Aromatic amines are usually weaker bases than aliphatic amines. Important reactions of aniline include *N*-alkylation, ring alkylation, acylation, condensation, cyclization, reaction with nitrous acid, oxidation, halogenation, sulfonation, and nitration. Aniline is toxic and may be fatal if swallowed, inhaled, or absorbed through the skin.

The most important manufacturing processes for aniline and other bulk arylamines are based on the continuous catalytic hydrogenation of nitro compounds employing heterogeneous copper, nickel, or platinum-group catalysts [6]. To produce more complex amines on a smaller scale, homogeneous catalysis, with its greater possibilities for chemo- and regioselective hydrogenation, is increasingly the method of choice. An alternative process for production of aniline and phenylenediamines is the nucleophilic amination of phenols or the catalytic amination of haloarenes.

Aniline in the pure (freshly distilled) state is a colorless liquid with a characteristic odor that is not nearly as obnoxiously fishy smelling as aliphatic amines. It readily autoxidizes in air and quickly discolors as soon as air has gained entry into the storage flask.

Aniline is an important intermediate in the chemical industry for the production of dyes, pharmaceuticals, and other aromatic compounds. It is an intermediate in the production of centralites (stabilizers for double-base propellants) and tetryl. Aniline itself has been proposed as a stabilizer and  $\text{NO}_x$  scavenger for solid propellants, but it is too volatile for that application. Aniline was used as an auxiliary fluid in the production of anhydrous hydrazine by azeotropic distillation, and inevitably a small percentage of aniline was carried over into the hydrazine product, causing several types of operating problems for hydrazine monopropellant thrusters (see *Encyclopedia of Monopropellants*). At one time, the MIL SPEC for monopropellant-grade hydrazine allowed up to 0.5% aniline, but that was sufficient to render the hydrazine of very limited use for certain long-term, low-duty-cycle missions where hydrazine was used as

a monopropellant at certain duty cycles. In order to produce Viking grade or high-purity grade hydrazine, the aniline had to be removed (by fractionated crystallization) or the water from hydrazine hydrate had to be removed by alternate dehydration processes not involving any aniline as the auxiliary fluid to break the hydrazine-water azeotrope.

## 2.1 Physical Properties of Aniline

The physical properties of aniline are listed in Table 3.

**Table 3:** Physical properties of aniline.

| Property                                                    | SI units                                 | Other units                                                                   | References |

The velocity of sound in aniline and mixtures of aniline and furfuryl alcohol was measured by a single-pulse technique at temperatures from 294 to 366 K (70–200 °F) and pressures of 0.1–4 MPa (1–40 atm) [14]. Values calculated for a mixture of aniline (80%) and furfuryl alcohol (20%) using the molar sound velocity concept of Rao agreed with the experimental values to within 10%.

### 2.1.1 Vapor Pressure of Aniline

The vapor pressure of aniline can be calculated from the Antoine equation

$$\ln p_{\text{sat}} = 6.2533 - 1590.91/(T - 82.81)$$

where  $p_{\text{sat}}$  is the saturation pressure in kPa and  $T$  is the temperature in kelvin. This is valid for the pressure range 20–200 kPa. A different Antoine equation for the vapor pressure of aniline in the range 304–457 K is

$$\log(P) = 4.34541 - [1661.858/(T - 74.048)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin [15].

Droplet evaporation experiments were performed with single drops of WFNA and of aniline on a hot surface in the temperature range from 573 to 1373 K (300–1100 °C) [16]. These drops showed initial evaporation periods, during which the diameters of the drops did not diminish. The influence of bubble inflation on the course of the evaporation, and in particular on the total evaporation time for a given initial diameter, was studied. The evaporation times were exponential functions of the temperature of the hot surface. It was demonstrated that, at constant temperature, the evaporation time per 1 mg of drops can be longer or shorter for nitric acid than for aniline depending on the actual value of the temperature.

### 2.1.2 Heat Transfer Coefficients of Aniline

The thermal conductivity of aniline is  $0.1774 \text{ W m}^{-1} \text{ K}^{-1}$  ( $4.24 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1}$ ) [8]. Other sources gave the thermal conductivity of liquid aniline at 293 K as  $0.1728 \text{ W m}^{-1} \text{ K}^{-1}$  ( $4.13 \times 10^{-4} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ }^{\circ}\text{C}^{-1}$ ) [13].

The heat transfer from an electrically heated tube to aniline was measured at high heat flux to simulate conditions in the cooling channels of regeneratively cooled rocket engines [17].

### 2.1.3 Thermodynamic Properties of Aniline

The thermodynamic properties of aniline are listed in Table 4. The heat capacities of aniline and aniline/furfuryl alcohol mixtures in the range 300–422 K (80–300 °F) were determined by calorimetric measurements because they were needed to calculate the regenerative cooling capability of this fuel in a rocket engine [18].

**Table 4:** Thermodynamic properties of aniline.

| Property                                                               | SI units                                           | Other units                                            | References |
|------------------------------------------------------------------------|----------------------------------------------------|--------------------------------------------------------|------------|
| Molecular mass                                                         | 93.1265 g/mol                                      | 10.738 mol/kg                                          | [7]        |
| Heat capacity                                                          | 2.063 J g <sup>-1</sup> K <sup>-1</sup> (at 298 K) | 0.493 cal g <sup>-1</sup> °C <sup>-1</sup> (at 25 °C)  | [11]       |

## 2.2 Molecular Structure of Aniline

Aniline (benzeneamine) has  $C_s$  ( $\sigma=1$ ) symmetry. From an investigation of the microwave spectra of  $C_6H_5NH_2$  and  $C_6H_5NHD$ , it was established that  $C_6H_5NH_2(G)$  has a non-planar structure in which the  $-NH_2$  plane (containing the nitrogen atom and its two attached hydrogens) makes an angle of about 40° with the plane of the phenyl ring. The molecular structure derived from microwave spectra of deuterated benzeneamine is such that the  $-NH_2$  group adopts an out-of-plane angle of  $37^\circ 29' \pm 2^\circ$ , with the  $\angle HNH$  angle being  $113^\circ 6' \pm 2^\circ$  [20].

## 2.3 Fuel Mixtures with Aniline

Because aniline is readily available, many different mixtures of aniline with other fuels have been tested in the hope of improving its hypergolic ignition characteristics (see the future *Encyclopedia of Hypergolic Bipropellant Combinations*). A fuel mixture of aniline with methylamine and hydrazine has been evaluated as a hypergolic fuel for use with WFNA or RFNA.

A 50:50 mixture of aniline and furfuryl alcohol was used in one version of the first American liquid propellant ballistic missile, the MGM-5 Corporal, developed by Jet Propulsion Laboratory (JPL), Douglas Aircraft, and Firestone Rubber for the US

Army and deployed during the years 1954–1964. It was capable of carrying a payload of 680 kg, including nuclear warheads. An early version of Corporal E used a fuel consisting of 80% aniline and 20% furfuryl alcohol. The later type II Corporal used a 46.5 mass-% aniline, 46.5 mass-% furfuryl alcohol, and 7 mass-% hydrazine mixture as the fuel and stabilized IRFNA with 14%  $\text{NO}_2$ , 2.5%  $\text{H}_2\text{O}$ , and 0.6% HF as the oxidizer [21, 22]. The heat capacity of the aniline/furfuryl alcohol mixture in the range 300–422 K (80–300 °F) was determined by calorimetric measurements because it was needed to calculate the regenerative cooling capability of this fuel in a rocket engine [18].

Hydrazine and aniline form a eutectic mixture that freezes at 237 K (–36 °C) and has the composition 17.3 mass-% hydrazine and 82.7 mass-% aniline (Figure 1). The low freezing point of this mixture makes this hypergolic fuel suitable for small missile applications.

**Figure 1:** Freezing point diagram of aniline-hydrazine mixtures. (Reproduced and modified from [23].)

The freezing points of hydrazine-aniline mixtures can be depressed to 233 K (–40 °C) or below by the addition of small quantities of a third component. The freezing points and other physical properties of the ternary fuel mixtures hydrazine-aniline-methylamine, hydrazine-aniline-ethylamine, hydrazine-aniline-diethylamine, hydrazine-aniline-triethylamine, hydrazine-aniline-ethyleneimine, hydrazine-aniline-methanol, hydrazine-aniline-ethanol, hydrazine-aniline-ammonia, and hydrazine-aniline-acetylene were investigated [23]. Using ethylamine and diethylamine as third components with the hydrazine-aniline system was found to give solutions that

freeze below 233 K (−40 °C). The eutectic hydrazine-aniline mixture absorbs only 3.6 mass-% ammonia or 0.98 mass-% acetylene at ambient temperature and pressure, and the resulting modest effects on the freezing point and ignition properties of the mixture were too slight to warrant the use of these additives.

## 2.4 Chemical Properties of Aniline

Aniline is mildly alkaline [24]. It is a weak base and reacts with strong mineral acids to form solid salts that are soluble in water. Aniline (anilinium, anilino) salts with oxidizing acids ( $\text{HNO}_3$ ,  $\text{HClO}_4$ ) are potentially explosive. Aniline is hypergolic with concentrated nitric acid, which is the main reason why it is (still) listed in this book.

Aniline is soluble in ether, ethanol, and most organic solvents. It is only slightly soluble in water, which dissolves 3.2 vol.-% aniline at 293 K.

Aniline is indefinitely storable in the absence of air and will not decompose at its normal boiling point. Freshly distilled, clear aniline will slowly autoxidize and become discolored from dissolved autoxidation products.

Of the nitro-substituted aniline derivatives, only 2,4,6-trinitroaniline (2,4,6-TNA, picramide) is of practical interest as an explosive (but not as a propellant ingredient). As an explosive, picramide has some advantages over picric acid because it is less soluble in water and less corrosive. The remaining ring hydrogens can also be replaced by nitro groups, forming tetranitroaniline or pentanitroaniline, but these compounds are too sensitive for practical use. 1,3,5-Triamino-2,4,6-trinitrobenzene (TATB) can formally be considered an aniline derivative although it is not made from aniline. It is an energetic compound with exceptionally good thermal stability, and new methods for its large-scale production are still being developed.

### 2.4.1 Analysis of Aniline

Occasional instant spot checks of aniline vapor concentration in the air at the workplace are most easily performed with gas detection tubes, which contain an indicator (supported on a granular material) that changes color when exposed to ammonia. Such tubes are available from Draeger, MSA, Kitagawa and other commercial sources. Gas detection tubes are sensitive to as little as 5 ppm aniline and can measure up to 60 ppm  $(\text{C}_2\text{H}_5)_3\text{N}$  with ten strokes. Draeger aniline gas detection tubes are available for two ranges of concentrations (Table 5).

One of the first storable liquid hypergolic fuels used in the United States was a mixture of aniline, hydrazine, and furfuryl alcohol. This mixture had to be analyzed frequently to verify its storability [26].

**Table 5:** Draeger aniline gas detection tubes.

| Tube designation | Concentration range | Draeger part number |
|------------------|---------------------|---------------------|
| Aniline 0.5/a    | 0.5–10 ppm          | 67 33 171           |
| Aniline 5/a      | 1–20 ppm            | CH 20 401           |

Data source: [25]

## 2.5 Handling of Aniline

Aniline is a weak base and does not cause chemical burns when spilled on unprotected skin. However, aniline is a strong blood poison and will cause cyanosis and degenerative changes in red blood cells. Handling instructions emphasize the importance of preventing skin contact because aniline is readily absorbed through the skin [27, 28]. Aniline spilled on the skin should be washed with lots of water, neutralized with 5% acetic acid, and rinsed again.

One of the symptoms of aniline poisoning is a bluish tinge of the tissues, cyanosis, which results from inadequate oxygenation of the tissues. Other symptoms of aniline poisoning are headaches, weakness, difficulty breathing, convulsions, and psychologically unstable behavior.

The vapor pressure of aniline is very low, and the fire hazard it presents is very low (Table 6).

**Table 6:** Fire hazard properties of aniline.

| Property                 | Method     | SI units                         | Other units      | References |
|--------------------------|------------|----------------------------------|------------------|------------|
| Flammable range          | —          | 1.2–8.3 vol.-% at 413 K = 140 °C |                  | [29]       |
| Flash point              | —          | 348.6 K                          | 168 °F = 75.5 °C | [19]       |
| Flash point              | Open cup   | 364 K                            | 195 °F           | [12]       |
|                          | Closed cup | 344–349 K                        | 160–168 °F       | [12]       |
| Autoignition temperature | —          | 800–1044 K                       | 980–1420 °F      | [12]       |
|                          | I-8        | 890 K                            | 617 °C           | [30]       |

## 2.6 Toxicity of Aromatic Amines

The vapor pressure of aniline is very low, such that the inhalation hazard is not very high. However, all of the anhydrous hydrazine used for toxicity studies in various toxicological laboratories in the US in the 1970s and 1980s contained substantial amounts (~0.5%) of aniline, which could have contributed as a synergistic toxicant to the observed effects attributed to hydrazine – a circumstance that toxicologists did not recognize at the time. The Occupational Safety and Health Administration (OSHA) per-

missible exposure limit (PEL) Threshold Limit Value (TLV) Time Weighted Average (TWA) for aniline is 5 ppm. The immediately dangerous to life and health (IDLH) concentration of aniline is 100 ppm [31]. Acute Exposure Guideline Levels for Selected Airborne Chemicals (AEGL) values were initially developed for 30 min and 1, 4, and 8 h exposures [32]. Since that time, AEGL values have also been developed for 10 min exposures. The criteria used in establishing acute exposure guideline levels for aniline are outlined in [32].

The aromatic amine of the most concern regarding toxicity is benzidine, a relative of aniline. Toxicity studies of aromatic amines have often compared these two amines [33–36]. Benzidine has been evaluated as a hypergolic fuel grain for hybrid rockets.

## 2.7 Properties of Anilinium Salts

### 2.7.1 Anilinium Nitrate

Anilinium nitrate forms colorless crystals with a melting point of 455–457 K (182–184 °C) that yield nitraniline when heated to 463 K (190 °C). The crystal density is 1.356 g/cm<sup>3</sup> at 277 K (4 °C) and the crystals are very soluble in water or ethanol. The crystals belong to the *Pbca* (no. 61) space group of the orthorhombic system,  $a = 10.158(2) \text{ \AA}$ ,  $b = 9.277(2) \text{ \AA}$ ,  $c = 16.177(3) \text{ \AA}$ ,  $Z = 8$  [37].

### 2.7.2 Anilinium Perchlorate

Anilinium perchlorate decomposes slowly when heated to 453 K (180 °C) and explodes at 523 K (250 °C). Anilinium perchlorate is a molecular ionic solid [38].

### 2.7.3 Anilinium Dinitramide

Anilinium dinitramide,  $[\text{C}_6\text{H}_5\text{N}^+\text{H}_3][\text{N}^-(\text{NO}_2)_2]$ , CAS RN [165603-95-2], melts at 368–370 K (95–97 °C) [39].

## 3 Ring-Substituted Aniline Derivatives

Substitution of one or more hydrogens at the 2-, 3-, 4-, 5- or 6-position on the benzene ring of aniline by substituents leads to a variety of amines that have potentially better rocket fuel properties than aniline itself. The substituents could be one or more methyl groups or additional amino groups. Additional nitro groups improve the overall oxygen balance of the molecule, all the way up to triaminotrinitrobenzene, a powerful and thermally stable explosive. The most common substituents are methyl groups, leading to toluidines (*ortho*, *meta*, and *para*) for monomethyl-substituted anilines and xylidines for disubstituted anilines. These amines are described in their own sections below. Ring-substituted alkyanilines are isomers of *N*-substituted anilines but they

differ in their properties. Both types can potentially be used as hypergolic rocket fuels in place of aniline or in combination with aniline and triethylamine.

The effects of ring substitution on the basicity of the substituted aniline free base and the thermal stability of the substituted anilinium nitrates are tabulated in Table 7 [40, 41]. The electron-sucking  $\text{NO}_2$  group decreases the basicity and decreases the thermal stability of the nitrate salt. The electron-pushing  $-\text{CH}_3$  and  $-\text{NH}_2$  groups increase the basicity and increase the thermal stability of the nitrate salt. The thermal stability and impact sensitivity of the *meta*- and *para*-substituted anilinium nitrates were found to be linearly related to the Hammett substituent constant  $\sigma$ , the basicity constant  $\text{p}K_{\text{a}}$ , and the oxygen balance of the corresponding nitrate salt.

**Table 7:** Effects of ring substitution on the basicity of the substituted aniline free base and the thermal stability of substituted anilinium nitrates.

| Substituent R                   | $\text{p}K$ of base | $\sigma$ | DTA exotherm, $^{\circ}\text{C}$ |
|---------------------------------|---------------------|----------|----------------------------------|

Date source: [41]

If aniline is used as a hypergolic fuel, the aryl nucleus may be oxidized by  $\text{NO}_2$  or  $\text{HNO}_3$  prior to ignition, and gaseous products are formed.

Ring-substituted arylammonium nitrates have been prepared and characterized to see what influence substituents have on the reactivity of the amino group [42]. Thermal and ignition characteristics of these solid salts were studied via thermogravimetric analysis (TGA) and ignition delay measurements. The ignition temperatures (IT) and energies of activation (ignition) ( $E_{\text{i}}$ ) (21.3–39.3 kJ/mol) were found to be linearly related to the Hammett substituent constant  $\sigma$ , the  $\text{p}K_{\text{a}}$  of the amine, and the oxygen balance of the corresponding nitrate salt. The results suggested that the primary step in the slow and rapid thermolysis of these salts is a proton transfer (NH bond heterolysis) from the arylammonium ion to the nitrate ion.

Thermolysis of ring-substituted arylammonium nitrates has been carried out by TGA and differential thermal analysis (DTA) [43]. Although the thermal decomposition kinetics of these salts were evaluated by fitting TGA data with nine mechanism-based kinetic models, the contracting envelopes ( $n = 2, 3$ ) and Avrami-Erofeev ( $n = 2, 3$ ) methods gave the best fit. The activation energies for decomposition, exothermic decomposition temperatures (from DTA curves), and impact sensitivity data were shown to be linearly correlated to the Hammett substituent constant  $\sigma$  and the dissociation constant exponent  $\text{p}K_{\text{a}}$  of the corresponding arylamine. A proposed reaction scheme ac-

counting for the observed products involves proton transfer, leading to the formation of an arylamine and  $\text{HNO}_3$  and oxidation of the arylamine by decomposition products of  $\text{HNO}_3$ . The oxidation-reduction reactions near the surface of the thermolysing material are responsible for the decomposition.

In a similar way, thermolysis of dimethylanilinium nitrates was studied by TGA, DTA, ignition delay, impact sensitivity, and friction sensitivity measurements [44]. Again, the Avrami-Erofeev ( $n = 2, 3$ ) and contracting area ( $n = 2$ ) methods gave the best fits to the data. The most probable reaction scheme that can account for the decomposition products involves a proton transfer leading to the formation of free arylamine and  $\text{HNO}_3$ . Other probable routes (with the evolution of  $\text{NH}_3$ ) have also been suggested. The aryl nucleus seems to be oxidized by  $\text{NO}_2$ ,  $\text{HNO}_3$ , or its decomposition products prior to ignition, and gaseous products are then formed.

Similar experiments were performed with the perchlorates of ring-substituted arylamines [45–47]. The decomposition and dissociation temperatures, as well as the activation energy for explosion, increase with increasing basicity constant  $\text{p}K_a$  of the corresponding arylamine. These parameters, when plotted against the Hammett substituent constant  $\sigma$ , showed a linear relationship in the case of *meta*- and *para*-substituted derivatives. The results indicated that a proton transfer from arylammonium ion to perchlorate ion is involved in the decomposition and explosion processes of these arylammonium perchlorates. The explosion temperatures, explosion delay, and activation energy for explosion were substantially lower for the 3,4-dimethylanilinium perchlorate compared with the 2,5- and 2,4-substituted salts.

### 3.1 Toluidines

Of the three isomeric toluidines

only the *ortho* isomer is suitable as a rocket propellant. The *meta* isomer is difficult to obtain and the *para* isomer is a solid at room temperature.

*o*-Toluidine (2-methylbenzenamine) is an important intermediate in the production of dyes and pharmaceuticals by the chemical industry. It is produced by reduction of *o*-nitrotoluene. *o*-Toluidine in mixture with triethylamine has been used as a rocket fuel [48]. In all fuel blends, toluidine gave shorter ignition delays than aniline.

In the pure state, *o*-toluidine is a colorless oily liquid, but in the presence of air and in bright light it autoxidizes readily and discolors to form a dark brown liquid. The physical properties of *o*-toluidine are summarized in Table 8 [3]. Additional properties of toluidines are available in the literature [49].

**Table 8:** Physical properties of *o*-toluidine.

| Property                           | SI units                          | Non-SI units                       | References |

The precautions necessary for the safe handling of toluidine are the same as those for aniline. Similar to aniline, toluidine is a blood poison.

Toluidine forms salts with strong acids. *o*-Toluidine dinitramide melts at 343–344 K (70–71 °C) [39].

### 3.2 Xylidines

Xylidines, dimethylaminobenzenes, C<sub>8</sub>H<sub>11</sub>N, molecular mass 121.1796 g/mol, CAS RN [1300-73-8], are dimethyl anilines in which the two methyl groups can occupy different positions on the ring and create up to six possible isomers. They must not be confused with the isomeric *N,N*-dimethylaniline. Xylidines are produced by reduction of nitroxylenes, which are a mixture of different isomers. The composition of the mix-

ture depends on the conditions during the nitration of xylene and the xylenes that are used for the nitration to start with. The nitroxyls and xylidines are usually not separated but are used as a mixture of isomers. Xylidines can be used as hypergolic rocket propellants in combination with triethylamine. Additional information on properties of xylidines is available in the literature [50]. Most xylidines are suitable as hypergolic fuels, but some are solids. The effect of the molecular structure of the xylidine on the ignition delay when used in combination with nitric acid has been studied in detail.

During World War II (WW-II), xylidine/triethylamine mixtures were used as hypergolic fuels with WFNA and RFNA [51]. These mixtures had code names such as Tonka, followed by a number.

*Furaline*, a hypergolic fuel used extensively by the French company Société d'Études de la Propulsion par Reaction (SEPR) in its experimental anti-aircraft missile SEPR-2, was a mixture of 41% furfuryl alcohol, 41% xylidine, and 18% ethanol [52]. Another fuel blend was called TX-2, which consisted of triethylamine and xylidine.

A hypergolic fuel mixture with the code name of *Samin* (*Samine*) and consisting of 50 mass-% xylidine and 50 mass-% triethylamine was widely used for several types of missiles in Russia (USSR) [53]. At the end of the Cold War, large quantities of this material had to be demilitarized in compliance with the SALT disarmament agreements [54]. Unfortunately, the storage conditions were not always carefully controlled, and some of the Samin had already leaked into the ground. The abandoned and decaying storage magazines constituted a hazard to the surrounding communities [55]. Various weapon systems used the Samin fuel blend and had to be demilitarized [56].

At one time, 290 metric tons of Samin (TG-02) containing 50% xylidine were stored at the Mingchevir depot in Azerbaijan, waiting for disposal. Color pictures of the unsafe conditions at the neglected storage sites are shown on page 19 of the Winkelmann thesis [57]. Where the fuel had leaked into the ground, it had formed a red-brown layer of xylidine autoxidation products, and the discoloration was sometimes only revealed if the top layer of drift sand was scraped and moved to the side. Several different methods to not only dispose of but also to convert abandoned and unwanted rocket propellants, including Samin and Melanj, into commercially useful products such as fertilizer or plastics were evaluated [58–61].

Xylidines are sensitive to autoxidation by atmospheric oxygen, resulting in an increased ignition delay. *N*-Isopropyl-*N'*-phenyl-*p*-phenylenediamine, *N*-cyclohexyl-*N'*-phenyl-*p*-phenylenediamine, and *N,N'*-diphenyl-phenylenediamine were evaluated as antioxidants of amine-based fuel components [62]. They almost totally inhibited the consumption of xylidine while significantly retarding the autoxidation of triethylamine. *N*-Isopropyl-*N'*-phenyl-phenylenediamine was the most effective of all the antioxidants studied, and addition of only 0.5 mass-% was sufficient to give the required autoxidation protection.

### 3.3 Trimethylanilines

There are no known uses of trimethylaniline free bases as rocket propellants, but their oxyacid salts have been evaluated as propellant ingredients.

Several nitrate and perchlorate salts of 2,4,6-trimethylaniline have been prepared and characterized by X-ray diffraction (XRD), gravimetric analyses, TGA, TGA/DSC, and their ignition/explosion delays [63]. It was observed that proton transfer from a substituted anilinium ion to nitrate and perchlorate ions regenerates free amine,  $\text{HNO}_3$ , and  $\text{HClO}_4$  in the condensed phase at higher temperature, where oxidation-reduction between the amine and acids leads to ignition and explosion. The kinetics of thermal decomposition were evaluated by applying model fitting as well as isoconversional methods. The activation energies of the decomposition of the nitrate and perchlorate salts were 77.9 and 118.2 kJ/mol, respectively.

## 4 Phenylenediamines

Phenylenediamines form phenylenediammonium dinitrate salts, which are quite energetic. Four different phenylenediammonium dinitrate salts were prepared and characterized by elemental analysis, infrared (IR), and ultraviolet (UV) spectroscopy [64]. These dinitrates can potentially find applications in propellants, explosives, and pyrotechnics. Their thermal decomposition was studied by TGA and simultaneous TGA-DSC. The decomposition leads often to ignition. In a similar study, phenylenediammonium diperchlorate salts were prepared and characterized, which are also very energetic and potentially explosive [65].

## 5 *N*-Substituted Aniline Derivatives

In addition to substituting aniline on the ring, the two hydrogens on the amino group of aniline can also be substituted, leading to aniline derivatives with potential value as hypergolic fuels. *N*-Substituted anilines can be produced from aniline by reaction with methanol under high pressure.

### 5.1 *N*-Methylaniline and *N,N*-Dimethylaniline

The hypergolic ignition of *N*-methylaniline or *N,N*-dimethylaniline is no better than that of aniline itself. These aniline derivatives were evaluated back in WW-II by the Germans but were never practically utilized [51]. Physical properties of *N*-methylaniline and *N,N*-dimethylaniline are summarized in Table 9.

**Table 9:** Physical properties of *N*-methylaniline and *N,N*-dimethylaniline.

|                                    | SI units                                 | Other units                                                                 | References |

| Boiling point                      | 467.2 K                                  | 194.1 °C                                                                    |            |
| Density                            | 960.1 kg/m <sup>3</sup> (at 288 K)       | 0.9601 g/cm <sup>3</sup> (at 15 °C)                                         |            |
| Index of refraction ( $n_D^{15}$ ) | 1.5608                                   | —                                                                           |            |
| Standard enthalpy of formation     | +63.60 kJ/mol                            | +15.2 kcal/mol                                                              |            |
| Heat of combustion, liquid         | 4784 kJ/mol                              | 1143.4 kcal/mol                                                             |            |

For comparison, the thermal conductivity of aniline is  $4.24 \times 10^{-4}$  cal cm<sup>−1</sup> s<sup>−1</sup> °C<sup>−1</sup>. *N*-Ethylaniline has been tested as a hypergolic fuel, but has never found flight applications [66–68]. Substitution of hydrogens on the nitrogen atom of aniline by alkenyl groups instead of alkyl groups may lead to amines with better hypergolic ignition properties than the amines with saturated alkyl substituents. *N,N*-Diallylaniline is not readily available but was nevertheless tested as a hypergolic fuel by National Advisory Committee for Aeronautics (NACA) in the post-WW-II era in the US, both on its own and in mixtures with triethylamine. Its ignition found to be more reliable than that of *N,N*-diethylaniline.

The drop sensitivity, friction sensitivity, and thermal stability of dimethylanilinium nitrates have been tested by DTA and TGA, and a fairly complex mechanism for decomposition reactions was proposed [44]. A proposed reaction scheme accounting for the decomposition products involved proton transfer leading to the formation of an arylamine and HNO<sub>3</sub>. Other probable routes (evolution of NH<sub>3</sub>) have also been suggested. The aryl nucleus seems to be oxidized by NO<sub>2</sub>, HNO<sub>3</sub>, or its decomposition products prior to ignition, and gaseous products are formed.

## 6 Diphenylamine

Diphenylamine, *N,N*-diphenylamine,  $C_6H_5NHC_6H_5$ ,  $C_{12}H_{11}N$ , DPA, CAS RN [122-39-4], and diphenylamine derivatives are used as  $NO_x$  getters ( $NO_x$  scavengers) and stabilizers in double-base propellants. Diphenylamine is a relative of aniline, a secondary amine where one of the hydrogens on the amino group of aniline has been replaced by an additional phenyl group [69].

Diphenylamine can be made by heating a mixture of aniline and anilinium chloride in an autoclave. Diphenylamine is readily available. It is sparingly soluble in water, but readily soluble in acids and in ethanol or acetone.

Diphenylamine is very useful as a  $NO_x$  scavenger and stabilizer for solid double-base propellants. As the result of the slow decomposition of double-base propellants and release of nitrous fumes, diphenylamine is partially and irreversibly converted to a mix of dinitrodiphenylamine isomers. However, diphenylamine can not only stabilize nitrocellulose; it may also react with it.

A tertiary aromatic amine, triphenylamine (TPA) was used for the first time as a stabilizer for double-base propellants in France in 1937. The stability of those samples was described as good. Around 1950, an American group produced TPA-stabilized propellants and investigated the decomposition mechanism. Apart from a single experiment in the 1970s, no further attempts were made to use TPA as a stabilizer for propellants until 2007, when a study gave somewhat encouraging results [70]. One advantage of using tertiary amines over secondary amines is that they are less likely to form toxic and carcinogenic nitrosamines when they act as  $NO_x$  getters.

### 6.1 Physical Properties of Diphenylamine

Diphenylamine forms soft, colorless crystals. Physical and thermodynamic properties of diphenylamine are listed in Table 10. The *NIST Chemistry WebBook* [7] gives several numbers for the enthalpy of formation of solid DPA; we assume that the most recent is the most reliable source of data.

The volatility of DPA is undesirable because it may cause a loss of stabilizer from double-base propellants during storage. Therefore, it is important to know the vapor pressure of DPA. The vapor pressure of DPA in the range 381.5–575 K can be calculated

from the following equation:

$$\log_{10} P = 5.09811 - [2729.385 / (T - 39.207)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. The IR spectrum of a 10% DPA solution in  $\text{CCl}_4$  is shown in Figure 2.

**Table 10:** Physical and thermodynamic properties of diphenylamine.

| Property                              | SI units               | Non-SI units                   | References |

## 6.2 Chemical Properties of Diphenylamine

The main use of diphenylamine in solid propellant formulations is as a  $\text{NO}_x$  getter ( $\text{NO}_x$  scavenger). By immobilizing the  $\text{NO}_x$ , premature decomposition and even (under extreme conditions) autoignition of aging and overheated double-base propellants can be avoided. However, stabilizer depletion has to be monitored. There are several analytical methods that allow the remaining unreacted diphenylamine in the propellant to be determined, making it possible to predict how many years the rocket can still be used before it needs to be retired. The reaction of diphenylamine with  $\text{NO}_x$  yields a mixture of 2,2'-, 2,4'-, and 4,4'-dinitrodiphenylamines.

## 6.3 Analysis of Diphenylamine

A variety of methods for analysis of diphenylamine in solid propellants are offered in MIL-STD 286C [74] (Table 11) and MIL-D-98A. Additional analysis methods are described in [75].

**Table 11:** Analytical methods for determination of diphenylamine in propellants.

| Title of analytical method                                                                                                 | No. of pages | Method number |
|----------------------------------------------------------------------------------------------------------------------------|--------------|---------------|
| <i>Diphenylamine (Gravimetric Method)</i>                                                                                  | 3            | 201.2.3       |
| <i>Diphenylamine (Solvent Extraction – Bromination Method)</i>                                                             | 2            | 201.1.4       |
| <i>Diphenylamine and Ethyl Centralite in Admixture or Separately (Steam Distillation Spectrophotometric Method)</i>        | 4            | 201.4.2       |
| <i>Diphenylamine or Ethyl Centralite (Steam Distillation Volumetric Bromination Method)</i>                                | 3            | 217.3.1       |
| <i>Diphenylamine and Ethyl Centrality in Admixture or Separately (Distillation Gravimetric and Volumetric Bromination)</i> | 4            | 217.4.1       |
| <i>Diphenylamine and Its Major Derivatives (HPLC Method)</i>                                                               | 5            | 217.5         |

Data source: [74]

High-performance liquid chromatography (HPLC) analysis with UV detection per Method 217.5 gives good separation of DPA and the reaction products of DPA with  $\text{NO}_x$  that may be found in aged propellant (Figure 3).

**Figure 3:** Typical HPLC fractogram of diphenylamine and its reaction products. (Reproduced and modified from [74].)

#### 6.4 Diphenylammonium Salts

The nitrate and perchlorate salts of diphenylamine have been prepared and characterized by elemental analysis, TGA, and DSC [76]. The proton transfer reaction plays a major role during thermolysis of these salts. On heating, the nitrate and perchlorate salts do not form ring-substituted nitro or perchloro derivatives; rather, they ignited and exploded, forming gaseous products along with some residual carbon.

### 7 *N*-Phenyl- $\beta$ -naphthylamine

When used as a stabilizer, *N*-phenyl- $\beta$ -naphthylamine has the advantage over diphenylamine that it has lower volatility. It is also used as an antioxidant in polymers and lubricants. *N*-Phenyl- $\alpha$ -naphthylamine is a suspected carcinogen [77].

## 8 *N*- and Ring-Substituted Aniline Derivatives

### 8.1 2-Nitrodiphenylamine

2-Nitrodiphenylamine, also known as benzeneamine 2-nitro-*N*-phenyl-, 2-nitro-*N*-phenylaniline, mononitrodiphenylamine,  $C_{12}H_{10}N_2O_2$ , 2-NDPA, CAS RN [119-75-5], is a widely used stabilizer in double-base propellants. 2-Nitrodiphenylamine is a red

crystalline solid, usually in the form of flakes or powder, with a melting point of 347–349 K (74–76 °C).

Solid double-base rocket propellant formulations with 2-nitrodiphenylamine as the stabilizer will be discussed in a future volume of the *Encyclopedia of Rocket Propellants*. The current chapter contains only the physical and chemical properties of 2-nitrodiphenylamine by itself.

2-Nitrodiphenylamine is made from *o*-chloronitrobenzene (OCNB) and aniline, but some of the raw material is sometimes inadvertently carried over into the product and eventually ends up in double-base propellants where 2-NDPA is used as a stabilizer. The contaminant OCNB has been reported to cause tumors in male and female rats.

## 8.2 Physical Properties of 2-Nitrodiphenylamine

The physical and thermodynamic properties of 2-nitrodiphenylamine are summarized in Table 12. Additional properties of 2-nitrodiphenylamine are listed in [78].

**Table 12:** Physical and thermodynamic properties of 2-nitrodiphenylamine.

| Property                         | SI units               | Non-SI units      | References   |
|----------------------------------|------------------------|-------------------|--------------|
| Molecular mass                   | 214.220 g/mol          | 214.220           | [7]          |
| Melting point                    | 348.1 K                | 75 °C             | [7]          |
| Density                          | 1.48 g/cm <sup>3</sup> | 0.0535 lb/cu. in. | [79]         |
| Oxygen balance                   | −201.7%                | —                 |              |
| Enthalpy of formation            | +121.0 kJ/mol          | +135 cal/g        | [79]         |
|                                  |                        | = +28.92 kcal/mol |              |
|                                  | +79.0 kJ/mol           | +88.13 cal/g      | [72], p. 327 |
|                                  |                        | = +18.88 kcal/mol |              |
|                                  | +77 ± 2 kJ/mol         | +18.4 kcal/mol    | [80]         |
| Heat of sublimation at 335–346 K | 100.9 kJ/mol           | 24.1 kcal/mol     | [7]          |
| Heat of combustion               | 6228 ± 2 kJ/mol        | 1488 kcal/mol     | [80]         |

### 8.3 Chemical Properties of 2-Nitrodiphenylamine

The major role of a stabilizer is to eliminate the acidic nitrates and nitrogen oxides produced by the gradual decomposition of nitric acid esters, which would otherwise autocatalyze further decomposition. Typically, 1–2% stabilizer is added to the propellant mixture; higher amounts than 2% degrade the propellant's ballistic properties. The amount of stabilizer depletes gradually with time; when the content drops from 2% to less than 0.5% NDPA, increased surveillance of the munition is required, and a content of less than 0.2% warrants immediate disposal, as the depletion of the stabilizer may lead to autoignition of the propellant during storage at high temperatures or in confined spaces. Other stabilizers of a similar aromatic amine pedigree are 4-nitrodiphenylamine, *N*-nitrosodiphenylamine, *N*-methyl-*p*-nitroaniline, and the unsubstituted diphenylamine.

#### 8.3.1 Reactions of 2-Nitrodiphenylamine

The reaction of 2-nitrodiphenylamine with  $\text{NO}_x$ , which occurs in aging double-base propellants, yields a mixture of nitration and nitrosation products.

#### 8.3.2 Analysis of 2-Nitrodiphenylamine

2-Nitrodiphenylamine that is intended to be used as a stabilizer in solid or liquid monopropellants must meet the requirements of *Military Specification MIL-N-3399B – 2-Nitrodiphenylamine* [81]. The minimum melting point allowed per this specification is 346 K (73°C). The maximum insoluble residue allowed in 95% ethanol is 0.2 mass-%, and the maximum allowed ash content is 0.1 mass-%.

The amount of 2-nitrodiphenylamine in a propellant can be determined by a titanium(III) chloride buffer method or by reaction with an excess of bromide/bromate and back titration of the excess bromine with iodide and standard sodium thiosulfate per MIL-STD-286C [82], Table 13. The spectrophotometric method determines the amount of 2-NDPA by measuring the absorption at 420–430 nm. Additional analytical methods are described in [78].

The nitration and nitrosation products of 2-nitrodiphenylamine (2-NDPA) were synthesized *in vitro*, mimicking their production in aging propellants by exposing 2-NDPA to gaseous  $\text{N}_2\text{O}_4$  or nitrous acid in various solutions and by nitration and oxidation of NO/2-NDPA [83]. Reactants and products were analyzed by preparative-scale liquid chromatography using a short  $\text{SiO}_2$  column and by UV-VIS and IR spectra.

Reversed-phase high-performance liquid chromatographic methods can be used for the determination of stabilizers including diphenylamine, 2-nitrodiphenylamine, and *N*-methyl-4-nitroaniline in double-base solid propellants, even in the presence of RDX, DANPE, or TAGN [84].

**Table 13:** Analytical methods for determination of 2-nitrodiphenylamine.

| Title of analytical method                                              | No. of pages | Method number |
|-------------------------------------------------------------------------|--------------|---------------|
| <i>2-Nitrodiphenylamine (Spectrophotometric Method)</i>                 | 2            | 218.4.3       |
| <i>2-Nitrodiphenylamine (Titanous Chloride – Buffer Method)</i>         | 2            | 218.2.1       |
| <i>2-Nitrodiphenylamine (Volumetric Bromination Method)</i>             | 2            | 218.1.2       |
| <i>2-Nitrodiphenylamine (Resorcinol – Liquid Chromatography Method)</i> | 3            | 218.5.1       |

Data source: [82]

A reversed-phase isocratic HPLC technique was used to separate 2-nitrodiphenylamine and its major reaction products with nitrogen oxide in double- and triple-base rocket and artillery propellants [85]. These compounds were determined in a single-base gun propellant during a storage period of 168 h at 100 °C using a developed and successfully verified HPLC method. See also [86].

#### 8.4 Safety Properties of 2-Nitrodiphenylamine

2-Nitrodiphenylamine that is leached from spilled propellant into the soil is only slowly degraded by soil bacteria [87].

### 9 *N*-Methyl-*p*-nitroaniline

*N*-Methyl-*p*-nitroaniline, also known as *N*-methyl-4-nitroaniline, 4-nitro-*N*-methylaniline, benzeneamine *N*-methyl-4-nitro-,  $\text{O}_2\text{NC}_6\text{H}_4\text{NHCH}_3$ ,  $\text{C}_7\text{H}_8\text{N}_2\text{O}_2$ , MNA, CAS RN [100-15-2], is used as a stabilizer in double-base solid propellants.

Studies indicated that 4-nitro-*N*-methylaniline is superior to centralite, 2-nitrodiphenylamine, or Acardite in stabilizing NC. 4-Nitro-*N*-methylaniline forms brownish-yellow prisms with violet reflections. It decomposes soon after it starts melting. Physical properties of MNA are summarized in Table 14.

The toxicity of MNA, measured as the LD50, is 400–800 mg/kg (mice, intraperitoneal) and 800–1600 mg/kg (mice, oral). MNA caused slight skin irritation in guinea pigs after 24 h of skin contact.

**Table 14:** Physical properties of *N*-methyl-*p*-nitroaniline.

| Property              | SI units                | Other units                |
|-----------------------|-------------------------|----------------------------|
| Molecular mass        | 152.1506 g/mol          | 6.5724 mol/kg              |
| Oxygen balance        | −168.3%                 | —                          |
| Melting point         | 424.8 K                 | 151.7 °C = 305 °F          |
| Density               | 1.190 g/cm <sup>3</sup> | 0.0430 lb/in. <sup>3</sup> |
| Enthalpy of formation | −31.4 kJ/mol            | −7.5 kcal/mol = −49 cal/g  |
| Heat of combustion    | 3867 kJ/mol             | 924.3 kcal/mol             |

## 10 Aromatic Nitramines

2,4,6-Trinitrophenylmethylnitramine, also known as tetryl, tetranitromethylaniline, empirical formula  $C_7H_5N_5O_8$ , CAS RN [479-45-8], with a molecular mass of 287.1 g/mol and an oxygen balance of −47.4%, forms pale yellow crystals. Tetryl is used as a powerful explosive, often as the booster pellet for card gap tests. It is not used in rocket propellants. The lead block indentation of tetryl is 410 cm<sup>3</sup>/10 g, as compared to 300 cm<sup>3</sup>/10 g for TNT and 483 cm<sup>3</sup>/10 g for RDX.

# Aromatic Hydrocarbons

## Introduction

*Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. The topic of hydrocarbon fuels had to be subdivided into several smaller sections that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are: “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.”

## 1 Aromatic Hydrocarbons

Aromatic hydrocarbons are organic compounds with typically six-membered rings where carbon atoms sometimes drawn as alternating double bonds actually share their electron clouds, giving the ring structure increased stability compared to alicyclic saturated hydrocarbon compounds. This type of structure is also called a “resonance structure.” The parent member of the family of aromatic hydrocarbons is benzene.

## 2 Benzene

Properties of aromatic hydrocarbons such as benzene, toluene, [1] and the xylenes are already listed in most readily available handbooks [2]. These data are readily accessible from the literature, so we have not included them in our listing of the properties of rocket propellants.

## 3 Toluene

Toluene,  $C_6H_5CH_3$ , methylbenzene, phenylmethane, CAS RN [108-88-3], may be found as a trace constituent in some kerosene-type products from petroleum refineries. Toluene has not often been used as a rocket fuel. Toluene was used in a rocket engine and compared to methylcyclohexane and heptane as the fuels [3].

Toluene is of interest as it is the product of the thermolysis of endothermic fuels such as methylcyclohexane. Toluene is the parent compound of a very widely used explosive, trinitrotoluene (TNT).

### 3.1 Physical Properties of Toluene

Toluene boils at 384.7K (110.6 °C). The dependence of the vapor pressure of toluene on temperature can be expressed by a Cox equation,

$$\ln\left(\frac{P}{P_c}\right) = \left(1 - \frac{1}{T_r}\right) \exp(2.32973 - 1.10646T_r + 0.73531T_r^2)$$

where the reduced temperature  $T_r = T/T_c$ ,  $T$  is the temperature in kelvin,  $T_c$  is the critical temperature (593 K), and  $P_c$  is the critical pressure (4109 kPa) [4].

#### 3.1.1 Thermodynamic Properties of Toluene

The results of heat capacity measurements of subcritical toluene at saturation pressure between 300 and 580 K were only given in table format in [4]. It would have been more practical to give the parameters for a curve-fitted polynomial equation.

### 3.2 Safety Properties of Toluene

#### 3.2.1 Limits of Flammability of Toluene

The flammable range of toluene vapor in air at 373 K is from 1.2 to 7.1 vol.-%.

#### 3.2.2 Flash Point of Toluene

The flash point of toluene is 277.5 K (4.4 °C).

#### 3.2.3 Autoignition Temperature of Toluene

The autoignition temperature of toluene in air is 841 K (568 °C = 1054 °F), which is much higher than that of any alkane hydrocarbon. Other sources give an autoignition temperature of 753 K (480 °C).

## 4 Xylenes

Xylenes are dimethylbenzenes. There are three isomers: *o*-xylene, *m*-xylene, and *p*-xylene. Xylenes have not been used as rocket propellants. Xylenes may be found as trace constituents in some kerosenes, depending on the source of the crude and the processing history.

## 5 Ethylbenzene

Ethylbenzene,  $C_6H_5C_2H_5$ , a homologue of toluene, is found as a natural constituent of petroleum and in gasoline and kerosene. Ethylbenzene can be synthesized from benzene and ethene. Most of the ethylbenzene is used for the production of styrene, an important monomer for the production of polystyrene. Ethylbenzene is not used as a rocket propellant.

# Azides and Azido Compounds

## Azides and Azido Compounds

This chapter contains information on inorganic and organic azides. The azide group carries extra energy that make these compounds useful as rocket propellant ingredients. In addition, many of these compounds contain a large amount of nitrogen, which makes them valuable as ingredients in nitrogen gas generators, such as in airbag inflators.

Azides contain three nitrogen atoms linked to each other in a very energetic, linear configuration. Theoretically the three nitrogen atoms could form a triangle, as in triaziridine, but that configuration is unstable. Most azides have a positive enthalpy of formation and decompose readily, liberating dinitrogen. The simplest azide, hydrogen azide, is a highly explosive and very toxic substance and has been the cause of many accidents. The following sections are subdivided into inorganic azides and organic azides. Both types of azides are being used in rocket propellant and gas generant formulations. Heavy metal azides are shock sensitive (stab sensitive) and are used as percussion primers in fire weapons. That application is not included in this book.

Early investigators assumed the shape of  $\text{N}_3^-$  azide ion to be a closed triangle, but other indications soon supported the linear structure of a chain of three nitrogen atoms. The open linear formula bore the perceived problem of a pentavalent middle nitrogen atom. This tripping point was later overcome by the resonance description of the azide ion: the nitrogen atom in the middle appears as iminium function, whereas the two terminal nitrogen atoms share the anionic charge. X-ray diffraction analyses and many other physical methods soon confirmed this open-chain structural formula of azides.

### 1 Inorganic Azides

The azide in solid inorganic azides exists as the  $\text{N}_3^-$  anion in a crystal lattice of anions and cations. In this configuration the azide ion is often grouped in the group of “pseudohalogenides” because it behaves like chloride or bromide or iodide, for instance in forming the insoluble silver salts. Inorganic azides, such as lead azide, are used as primary explosives (percussion initiators) and other azides, such as sodium azide, are used as sources of nitrogen in gas generants, predominantly those used for inflation of airbags in automobiles. We are not planning on providing a complete list of heavy metal azides like those used as primary explosives. Our inclination is to stay as far away from those as possible and take all necessary steps to prevent the inadvertent formation of shock-sensitive and friction-sensitive azides while preparing and using other azides.

The experimentally well-characterized covalent halogen azides ( $\text{XN}_3$ , where  $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{I}$ ) are a group of energetic compounds that could potentially be used as oxidizers if only they were not so sensitive. There are also highly unstable N-bound azides such as  $\text{ON}-\text{N}_3$  and  $(\text{FSO}_2)_2\text{N}-\text{N}_3$ , but those are only of academic interest.

The primary purpose of this section on inorganic azides is to summarize the properties of solid azides that are useful sources of nitrogen in gas generants.

In addition to the most frequently used sodium azide, many other azides have been synthesized in an effort to obtain improved nitrogen output or higher energy content. The most interesting inorganic azides are those of ammonium and hydrazinium, compounds consisting only of nitrogen and hydrogen. Both have been evaluated as rocket propellants.

Ammonium azide, hydrazinium azide, and other inorganic azides are described in a comprehensive summary on inorganic azides [1]. Table 1 is a summary of the nitrogen content of inorganic azides.

**Table 1:** Nitrogen content of inorganic azides.

| Compound name     | Formula                          | CAS RN     | M<br>g/mol | Nitrogen content<br>Mass-% |
|-------------------|----------------------------------|------------|------------|----------------------------|
| Lithium azide     | $\text{LiN}_3$                   | 19597-69-4 | 48.96      | 85.83                      |
| Sodium azide      | $\text{NaN}_3$                   | 26628-22-8 | 65.01      | 64.64                      |
| Potassium azide   | $\text{KN}_3$                    | 20762-60-1 | 81.1184    | 51.80                      |
| Ammonium azide    | $\text{NH}_4\text{N}_3$          | 12164-94-2 | 60.059     | 93.29                      |
| Hydrazinium azide | $\text{N}_2\text{H}_5\text{N}_3$ | 14662-04-5 | 75.08      | 93.28                      |

## 1.1 Alkali Metal Azides

Alkali metal azides are useful as sources of nitrogen. All alkali metal azides are very toxic, comparable to potassium cyanide. Literature summaries on azides will provide the reader with additional information on these substances [1–3].

### 1.1.1 Lithium Azide

Lithium azide can be prepared by metathetical reactions starting with the readily available sodium azide

### 1.1.2 Sodium Azide

Sodium azide,  $\text{NaN}_3$ , CAS RN [12136-89-9] or [26628-22-8], is widely used as a source of nitrogen in airbag inflators. With a nitrogen content of 64.6 mass-% N it is a good

source of nitrogen in gas generants. Sodium azide is the most frequently produced and most used alkali metal azide. There would be much more information on sodium azide available from a wide variety of sources than can be presented here. The current section is only an incomplete sampling of some of the information, just a way to get started.

### 1.1.2.1 Production of Sodium Azide

Sodium azide is produced by reaction of sodium amide with nitrous oxide

### Coatings for Sodium Azide

Coatings were developed for various types of azides, to protect them from ambient moisture and carbon dioxide or to reduce their volatility, as was recommended for ammonium azide.

One would hesitate to mix sodium azide with an acid (any acid) for fear of releasing hydrogen azide. Thus, it is unclear what motivated some investigators to coat sodium azide with stearic acid. Although stearic acid is a good pelletizing aid if gas generants for airbag inflators need to be pelletized, it is still an **acid** [4]. Although stearic acid is a weak acid, there is always the potential of liberating free hydrogen azide and getting into trouble. The other coating material tested was nitrocellulose [5]. The results of these experiments showed that the decomposition temperature of nitrocellulose coated sodium azide was about 50 °C higher than that of the pure sample.

### 1.1.2.2 Physical Properties of Sodium Azide

Physical properties of sodium azide are summarized in Table 2.

**Table 2:** Physical properties of sodium azide.

| Property              | SI units                                   | Other units                                   | References |

| Enthalpy of formation | +21.76 kJ/mol                              | +80 cal/g = +5.2 kcal/mol                     | [7]        |

### Solubility of Sodium Azide

The solubility of sodium azide in water is 38.9 g/100 mL (at 273 K = 0 °C), 40.8 g/100 mL (at 293 K = 20 °C), and 55.3 g/100 mL (at 373 K = 100 °C). Sodium azide is very solu-

ble in ammonia and somewhat soluble in methanol (2.48 g/100 mL at 298 K = 25 °C) or ethanol (0.22 g/100 mL at 273 K = 0 °C).

### Thermodynamic Properties of Sodium Azide

Standard enthalpies of formation of groups of inorganic and organic azides were calculated based on data for crystalline and aqueous ammonium azide and silver azide [8]. Data are presented for  $[\text{Me}_4\text{N}]\text{N}_3$  and  $[\text{Et}_4\text{N}]\text{N}_3$ , also in comparison to  $[\text{Me}_4\text{N}]\text{NO}_3$  and  $[\text{Et}_4\text{N}]\text{NO}_3$ .

### Molecular Properties, Crystal Structure, Dipole Moment of Sodium Azide

Sodium azide is an ionic solid. Two crystalline polymorphs are known, one rhombohedral and the other hexagonal. Both adopt layered structures [9].

Three pressure-induced phase transitions of sodium azide were observed by *in situ* synchrotron XRD measurements in a diamond anvil cell up to 52.0 GPa at room temperature [10]. The phase transition pressures were 0.3, 17.3, and 28.7 GPa. The first high pressure phase,  $\alpha\text{-NaN}_3$  (0.3 ~ 17.3 GPa), was identified to be monoclinic with a  $C_{2/m}$  space group. The  $\beta\text{-NaN}_3$  to  $\alpha\text{-NaN}_3$  transition is a second-order phase transition, accompanied by the shearing of the Na-layers and the tilting of the azide chains. The second high-pressure phase,  $\gamma\text{-NaN}_3$  (18.4 ~ 28.7 GPa), had a lower symmetry than  $\alpha\text{-NaN}_3$ . A further phase transition of  $\gamma\text{-NaN}_3$  to  $\delta\text{-NaN}_3$  at 28.7 GPa was observed.

#### 1.1.2.3 Chemistry of Sodium Azide

##### Reactions of Sodium Azide with Other Compounds

The oxidation of azide by ozone has been studied as one method of azide disposal and clean-up if azide (e.g., from airbag inflators) is accidentally spilled into surface waters [11]. Another method for the disposal of azide is the reaction with sodium hypochlorite [12]. The reaction stoichiometry is:

and proceeds by a key intermediate chlorine azide,  $\text{ClN}_3$ , which subsequently decomposes by reaction with a second azide molecule in the rate determining step:

Another method for disposal of azide ions in aqueous solutions is by catalytic hydrogenation [13].

### Thermal Decomposition of Sodium Azide

Sodium azide is thermally more stable than any of the organic sources of nitrogen in nitrogen gas generants, such as the ones used in airbag inflators. A good summary of the thermal decomposition of sodium azide and other metal azides is provided in

[14]. The rate of decomposition of sodium azide was proportional to the surface area of the reacting crystals. Reaction commenced at the edge of thin crystals and proceeded inwards parallel to the azide ions.

A study of the kinetics of thermal decomposition of sodium azide crystals provided experimental results for the rates of decomposition, which fell into three temperature regions: **(1)** below 573 K (300 °C); **(2)** 573–618 K (300–345 °C); and **(3)** above 623 K (350 °C) [15, 16]. Below 573 K (300 °C) the rate followed a linear relation after a rapid initial stage, leaving a white residue in the shape of the original crystal. The reaction began on preferred crystallographic faces and moved along a two-dimensional path towards the center of the crystal. During the progress of decomposition, a sharp line of demarcation was observed at the undecomposed azide and white residue interface. Between 573–618 K (300–345 °C) the rate was of the sigmoid curve shape, leaving white residue enclosing a central cavity. Above 623 K (350 °C) two different linear rates were observed, the latter being 100 times faster than the former with no detectable residue. The enhanced rate was attributed to adsorbed elemental sodium which catalyzes the reaction.

There is evidence that the decomposition takes place over a surface or interface which moves into the crystal in a preferred crystallographic direction. It is the area of this surface which controls the rate of decomposition [17]. The kinetics of thermal decomposition of sodium azide were dependent on the specific surface area of crystals [18]. Decomposition commenced at the edges of crystal platelets and advanced inward in directions parallel to the alternating planes of sodium and azide ions. The acceleration and decay of the decomposition after an initial first stage was dependent on the development of a closed two-dimensional envelope at the crystal edges and a subsequent contraction of the envelope. The boundary between decomposed and undecomposed material was indicated by three colored zones of the sodium decomposition product in different states of aggregation. With crystals grown slowly from aqueous solutions a residue remained when crystals were decomposed at temperatures up to 643 K (370 °C). At temperatures higher than 643 K (370 °C), where NaOH is appreciably volatile, little residue remains.

The thermal decomposition of sodium azide has been investigated by monitoring changes in dielectric constant, dielectric loss, and pressure with time at a fixed frequency during decomposition at 535–578 K (262–305 °C), and by monitoring changes in dielectric properties with frequency in the range 100–300 kHz for samples cooled to 293 K (20 °C) after partial decomposition at 563 K (290 °C) [19]. Three stages of decomposition could be identified for  $\alpha < 0.02$ , and activation energies for the three stages and for two types of sodium azide varied between 117 and 307 kJ/mol (28.0 and 73.4 kcal/mol).

Sodium azide doped with 1 mol-% potassium azide or 1 mol-% cesium azide showed a significant shortening of the induction period for decomposition at above 573 K (300 °C), but a lengthening of the induction period at low temperatures [20].

The extent to which cations affect the decomposition of sodium azide depends on their ionic radii. A similar effect was noted as the result of doping with  $\text{Ba}^{++}$  or  $\text{Hg}^{++}$  ions [21].

Differential thermal analysis and thermogravimetric analysis of sodium azide diluted with sodium chloride both showed one major peak followed by a second minor one [22]. This was interpreted as indicating the occurrence of two distinct decomposition processes. The activation energy of the first major process was 36 kcal/mol, which agreed with values reported previously from measurements of the rate of nitrogen evolution. Differential thermal analysis of sodium azide mixed with alumina was complicated by the presence of variable amounts of water adsorbed on the alumina. The presence of water was shown to have an inhibiting effect on the decomposition.

The thermal decomposition of sodium azide has been studied in the temperature range 513–633 K (240–360 °C) in vacuum and under pressure of an inert gas, argon [23]. The results showed that the decomposition is only partial at temperatures below 633 K (360 °C). It was found that: **(1)** the decomposition is incomplete both under vacuum and inert gas; **(2)** mass spectrometric studies did not reveal any decrease in the intensity of the background species,  $\text{CO}_2^+$ ,  $\text{CO}^+$ ,  $\text{H}_2\text{O}^+$ , and **(3)** sodium metal remained in the “free state” as seen by the formation of a metallic mirror at temperatures above 573 K (300 °C). It has been argued that the partial nature of decomposition is due to the confinement of the decomposition to intermosaic regions within the crystal lattice.

The effects of dopants and pretreatment, mechanical and thermal pretreatment, on the thermal decomposition of sodium azide have been investigated with a view to understanding the role of crystal imperfections in the decomposition [24]. It was observed that aliovalent ions,  $\text{Ba}^{2+}$  and  $\text{SO}_4^{2-}$  ions, as well as precompression, sensitized the decomposition while preheating lowered the decomposition rate. The effects were then discussed in terms of the dependence of the decomposition rate upon the concentration of gross imperfections in the sodium azide crystal lattice.

When the thermal decomposition of sodium azide was investigated in the temperature range 513–638 K (240–365 °C), 3 values for the activation energy, 155, 247, and 58 kJ/mol (37.0, 59.0, and 14 kcal/mol) were obtained, depending on the temperature range studied [25]. The mechanism of decomposition seems to involve excited azide ions (through internal conversion) and excitations. The activation energy of 58 kJ/mol (14 kcal/mol) appears to be associated with the promotion of electrons in the presence of sodium metal.

Gaseous azide radicals at concentrations up to  $10^{13}$  molecules  $\text{cm}^{-3}$  appear to have been generated in a flow system during the thermal decomposition of solid  $\text{NaN}_3$  at temperatures between 423 and 623 K (150 and 350 °C) [26]. Between 423 and 523 K (150 and 250 °C), the activation energy for the decomposition was  $0.80 \pm 0.15$  eV. The addition of small concentrations of oxygen atoms to the reactor excites NO  $\gamma$ -band chemiluminescence from the reaction

The  $\gamma$ -band emission may be used as a sensitive tracer for  $N_3$  in kinetic measurements;  $k_4$  was determined to be  $(10 \pm 4) \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ . Large concentrations of O atoms quantitatively convert the  $N_3$  to NO, and the resulting O/NO afterglow has been used to determine absolute concentrations of the  $N_3$  radicals. Several other chemiluminescent emissions are observed, most notably the nitrogen first-positive emission excited in azide-radical recombination.

The decomposition characteristics of  $\text{NaN}_3$  are variable and depend on parameters such as the particle size and shape, heating rate, defect concentration, and purity. The catalyzed thermal decomposition of  $\text{NaN}_3$  was found to be remarkably sensitive to metal oxides that may be present as contaminants. The effect of  $\text{Mn}^{2+}$  doping on the thermal decomposition of sodium azide has been studied [27]. It was found that  $\text{Mn}^{2+}$  is acting as an electron donor in compositions with some intermediate reaction occurring.

Evaluating another catalyst, a series of  $\text{NiO}/\text{Co}_3\text{O}_4$  mixed oxides in different ratios, 0.1–50 mol-%, were prepared by an impregnation method and tested for their activity in  $\text{NaN}_3$  decomposition [28].

The thermal decomposition of sodium azide was studied by thermal analysis to isolate effects caused by the gas atmosphere species, gas pressure, sample type (powdered or tablet), particle size, sample weight, surface heterogeneity, additives, and pre-aging [29]. Very complicated reaction mechanics arose if those effects were combined. It became evident that heat and mass transfer effects must also be considered when evaluating the thermal reactivity of sodium azide and its mixtures.

Manganese(IV) dioxide acts both as a catalyst and as an oxidizer in the decomposition of sodium azide, a reaction that is of interest for the use of sodium azide in airbag inflators [30]. Both  $\text{MnO}_2/\text{NaN}_3$  binary mixtures and  $\text{MnO}_2/\text{NaN}_3/\text{SiO}_2$  ternary mixtures were studied by thermal analysis, measurement of gas evolution, heat of reaction and burning rates. On heating, the thermal reaction for all mixtures started at 673 K (400 °C). The onset temperature was not sensitive to the mixture ratio of oxides and sodium azide.  $\text{MnO}_2$ -rich formulations produced some nitrogen oxides.

The effect of the surrounding gas atmosphere on the thermal decomposition of sodium azide was examined by thermal analysis, electrical conductivity measurement during heating and hot-stage microscopic observations [31]. Microscopic observations showed that the decomposition of  $\text{NaN}_3$  occurred regardless of the type of atmosphere surrounding it. The electrical conductivity increased with increasing temperature and suddenly became unmeasurably large (metallic sodium) when the temperature reached 653 K (380 °C).

The thermal decomposition of sodium azide with and without addition of metal oxide catalysts was studied by a combined differential thermal analysis-thermogravimetric analysis (DTA-TGA) method [32]. The onset of decomposition temperature was reduced by addition of metal oxides like  $\text{Fe}_2\text{O}_3$  and  $\text{SiO}_2$ . Similar reactions take place in airbag inflator gas generants.

The thermal decomposition of sodium azide and its mixtures was examined by DTA and the energy of activation,  $E_a$ , and pre-exponential factor,  $A$ , were calculated by the Kissinger and Ozawa equations [33].

#### 1.1.2.4 Handling of Sodium Azide

##### Transportation, Storage, and Disposal of Sodium Azide

Disposal of sodium azide in decommissioned airbag inflators has become a serious worldwide safety problem [34]. The primary approach was to activate the airbag inflators in the automobiles remotely from a safe distance before beginning to dismantle and shred the automobiles in the wrecking yards. It was assumed that the controlled activation and combustion consumes all azide contained in the gas generant and that there are no unburnt azide residues in the inflator and its filters. The section on reactions of azides (Section 1.1.2.3) contains several chemical reactions that are suitable for the disposal of azide.

#### 1.1.2.5 Toxicity of Sodium Azide

The literature on sodium azide toxicity was reviewed and summarized in several publications [35, 36]. Many of the toxic and environmental effects listed here for sodium azide would apply to other alkali metal azides as well. There is just more information on sodium azide than on the other azides. The active and toxic ingredient in all those cases is the azide ion, not the metal ion. The toxicity of sodium azide was a major concern during the development of gas generants for airbag inflators. Excessive concern about the toxicity of sodium azide may have forced the airbag inflator industry to switch to azide-free gas generants, some of which, in particular the ammonium nitrate-based gas generants, turned out to have other, more deadly side effects.

##### Acute Toxicity of Sodium Azide

The toxicity of azides is due to inhibition of cytochrome C oxidase in the blood. Azide inhibits cytochrome oxidase by binding irreversibly to the heme cofactor in a process like the action of carbon monoxide. Sodium azide particularly affects organs that need oxygen for high metabolism, such as the heart and the brain. Methods developed during medical surveillance of workers in sodium azide processing plants can also be applied to workers involved with other azide chemicals, e.g., glycidyl azide polymer (GAP).

The widespread use of sodium azide in airbag inflators has increased the risk of accidental exposures both during the manufacturing, active use, and eventually the disposal of airbag inflators [37].

The development of an occupational health surveillance and exposure control system for a chemical manufacturing plant making sodium azide has had to confront biological and hygienic difficulties related to the toxic nature of sodium azide. Sodium azide in pellet form was to be used as the nitrogen gas generant for automobile air

bags, but before it could be pelletized, it was manufactured as a very fine powder, liable to be carried away as dust, making exposure control more difficult. Sodium azide is a rapidly active, hypotensive agent that causes headaches and sudden drops in blood pressure. Occupational health assessment of the plant and its employees demonstrated the need for exposure control, based on inspection, interviews, health data, process review, and site review [38]. Engineering control and personal hygiene changes were developed in response to the evidence of worker exposure revealed by the studies.

Until 1996 there was no published literature describing occupational exposures to sodium azide in the rapidly growing automobile airbag inflator manufacturing industry. In 1994–1995, the National Institute for Occupational Safety and Health (NIOSH) conducted a cross-sectional study of health complaints reported by sodium azide production workers at the only continuous sodium azide production facility in the United States. The NIOSH evaluation consisted of a plant industrial hygiene survey, a symptom questionnaire, ambulatory blood pressure monitoring, and blood azide analysis [39]. Personal breathing zone air monitoring revealed exposures to sodium azide and hydrazoic acid at levels greater than the NIOSH recommended exposure limits (RELs). In some cases, exposures exceeded the REL despite the use of air-supplied respirators. The questionnaire revealed that most workers reported headache (10 of 11, 91%), episodes of low blood pressure (9 of 11, 82%), and palpitations (8 of 11, 73%) occurring in the production areas within the 6 months preceding the study. Mild headache (4 of 11, 36%) was the only symptom reported during a 24-h medical survey.

Despite its known toxicity and extensive current industrial use, the occupational neuropsychotoxicology of sodium azide had not yet been investigated until 2003. Neuropsychological and psychological tests, a symptom self-report questionnaire and hematological and cardiac measurements were gathered from 41 exposed workers and 42 unexposed workers in a chemical production plant annually for 3 years [40]. The exposed workers presented significantly more acute symptoms of exposure (headache, vertigo, nausea, fatigue, cardiac palpitations, irritated or red eyes) than did the unexposed workers; however, only one chronic symptom was repeatedly and more significantly reported, namely trembling of the hands. No psychological or neuropsychological tests (reaction time, psychomotor, cognitive, chromatopsia, profile of mood states) differentiated the two groups; however, acute effects of exposure on plasma creatinine and on systolic pressure were noted.

Table 3 is a summary of acute toxicity tests performed in test animals with hydrogen azide and sodium azide under various conditions of administration and with gradually increasing doses. The main objective of these tests was to determine the LD50 dosage or the LC50 concentration in air at which 50% of the test animals did not survive. This table is a summary compiled from nine different sources in the literature.

**Table 3:** Acute toxicity of hydrogen azide and sodium azide in animal tests.

| Test animal           | Mode of administration | Dose                 | Response, result        |
|-----------------------|------------------------|----------------------|-------------------------|
| <b>Hydrazoic acid</b> |                        |                      |                         |
| Mouse                 | Intraperitoneal        | 21.5 mg/kg           | Lethal dose             |
| Rat                   | Inhalation             | 849–967 ppm          | 0/14 died in 60 min.    |
| Rat                   | Inhalation             | 1024 ppm             | 3/8 died in 60 min.     |

### Mutagenicity of Sodium Azide

Besides concern about acute and chronic toxicity effects of azides, there has been increased concern about possible mutagenic, teratogenic or carcinogenic effects of azides in mammals in general and in humans in particular; however, up to this time there are no indications that azides are mutagenic, teratogenic or carcinogenic in ei-

ther test animals or humans. During 1977, while certain members in US Congress actively opposed the introduction of airbags with azide inflators as a safety device in automobiles, a controversy evolved about mutagenic effects of azides on plants and bacteria and the implication of tests with plants and bacteria relative to the widespread use of azides in airbag inflators and potential exposure of automobile occupants to azides. The following information may assist in a critical evaluation of potential hazards in the use and disposal of azides in airbag inflators.

### Azide Mutagenicity in Bacteria

The test most commonly used to detect bacterial mutagens is the Ames test. This test is also used to screen materials for potential carcinogens. The mutagenesis test originated in a system developed by Dr. Bruce N. Ames and his co-workers at the University of California in Berkeley. Specially developed strains of *Salmonella typhimurium* which cannot grow without the essential amino acid histidine were selected for this test. The bacteria are placed onto a nutrient medium containing the suspected mutagen and all essential components except histidine. For growth to occur, the bacteria must mutate (revert). Mammalian liver enzymes can be added as a model for metabolic action. These enzymes convert potential mutagens into active forms. Sodium azide at  $10^{-4}$  M concentration was reported to cause a 30-fold increase in reversion rate in several strains of *S. typhimurium* and a similar increase in reversion rate for the histidine-requiring *Escherichia coli* strain WP2s. Azide treatment slightly increased the frequency of occurrence of penicillin-resistant and streptomycin-resistant mutants in *Staphylococcus aureus*. Results with several different types of *S. typhimurium* mutants have shown that azide is a base substitution mutagen [42–44]. The mutagenic action may not be due to azide, but to one of its metabolites. One mutagenic azide metabolite is L-azidoalanine,  $\text{N}_3\text{CH}_2\text{CH}(\text{NH}_2)\text{COOH}$  [45]. Treatment of DNA with hydrogen azide at pH 2.8 resulted in the release of the purines guanine and adenine from DNA [46]. The release of guanine and adenine was not observed at pH 7.0. In *E. coli*, azide is most effective as a mutagen in stocks defective for excision repair [47].

### Azide Mutagenicity in Plants

The mutagenic activity of sodium azide has been put to good use to develop new strains of grain (barley). Azide has been shown to be a potent mutagen in barley [48]. The mutation data suggested that azide may only act on replicating DNA. Azide has also been reported to be an effective mutagen in peas, rice, *Triticum monococcum* and soybeans. In barley, azide at pH 3 greatly increased mutation frequency but had no effect at pH 11. Studies of mutation frequency on germinating barley seeds suggest azide may act only on replicating DNA. These results, in connection with the experiments on bacteria suggest two things. First, hydrogen azide ( $\text{HN}_3$ ), rather than sodium azide is the mutagen. Further studies with plant tissue from tobacco leaves have shown that in plants, neutral compounds like sodium azide are not able to penetrate the epidermis, but hydrogen azide can penetrate this barrier. This may explain the pH dependence of

mutation frequency. The second result is that azide appears to induce a point mutation by removing a purine (especially adenine) from DNA. There is no gross change in the DNA or addition of extra bases to the DNA.

The mutagenic action of azide was studied in many different plant species, including oats [49], barley [50] and rice [51].

### **Azide Mutagenicity in Human Cell Cultures**

The mutagenicity of sodium azide in both higher plants and bacteria is well documented; however, in mammalian cells, research on the effects of azide on gene mutations has produced conflicting results. Sodium azide acted cytostatically to cytotoxicity on 2 lines of mammalian cells [52]. After application of the substance in an acidic environment the highest cytostatic effect was noted. The results of the DNA synthesis inhibition test suggested that sodium azide does not damage the DNA of the observed fibroblasts with any of the tested modes of application. In Chinese hamster cells, neither 20-h treatment in medium nor 60-min treatment in an acid environment gave rise to significantly increased occurrence of 6-TG-resistant mutations.

### **Carcinogenicity of Sodium Azide**

Based on animal tests, sodium azide is not a proven carcinogen.

### **Bacteriostatic Activity of Sodium Azide**

Sodium azide solutions are used to disinfect medical equipment (blood cell counters, dialysis equipment) and to sterilize aqueous fluids used in medical analytical and diagnostic methods where pathogens are killed without leaving any residue. Unfortunately, this use in medical laboratories has resulted in several fatal accidents. Azide destroys gram-negative bacteria, enabling the cultivation of streptococci in diagnostic tests [53].

Ammonia nitrogen remains in the soil longer than nitrate nitrogen that is readily leached from the soil by rain and irrigation water. Azides kill nitrifying soil bacteria that convert ammonia (ammonium) to nitrate and thus allow nitrogen fertilizer to remain in the soil longer so it can be absorbed by the roots of agricultural crop plants [54].

#### **1.1.2.6 Accident History of Sodium Azide**

In a review of accidental poisonings, most of the reported cases involved persons working in hematological laboratories with blood cell counters. The time between azide exposure and detection of hypotension can predict outcome. Fatal doses occurred with exposures of 700 mg (10 mg/kg). Non-lethal doses ranged from 0.3 to 150 mg (0.004 to 2 mg/kg) [35]. All victims with hypotension lasting for more than 1 h died.

The following is a collection of literature references and case histories in chronological order [55–60]. New approaches were sought for the treatment of this cause of

accidental human poisoning [61, 62]. Three fatal sodium azide poisonings were reported in 1989 [63]. Several patients in a dialysis center suffered hypotension when residual azide after sterilizing the equipment entered their bloodstream [64]. There has been a rare sodium azide poisoning by skin contact and dermal absorption of sodium azide [65].

#### 1.1.2.7 Environmental Effects of Sodium Azide in the Soil

The environmental fate of sodium azide is of considerable interest given the widespread distribution in automobile air bag inflators. Since the mid-1990s, demand for sodium azide has exceeded 5 million kg per year and most passenger vehicles sold in the United States between 2000 and 2010 contained approximately 300 g (~0.7 lb) of sodium azide [66]. This has greatly increased the potential for accidental environmental releases and for human exposure to sodium azide. This is because not only are millions of kilograms of sodium azide now transported to and processed at air bag inflator factories, but it is also widely distributed throughout the developed world in automobiles. Even if sodium azide were to be replaced by a more benign propellant in the future, the problem of safely disposing of large quantities of azide will remain as the vehicle fleet ages and is retired to scrap yards and shredders. Additional work is required to study the environmental fate of sodium azide at the end of its road trip.

Azides (mostly potassium azide) have been used for the control of nematodes in root crops (carrots, potatoes) by pre-planting application to the soil and covering the soil with plastic to contain the hydrazoic acid fumes until the seeds or tubers are planted [67, 68]. The decay of azides in the soil during this application has been studied extensively and it has been shown that there are no lasting adverse side effects to crops harvested after the azide has decayed.

Azides (sodium and potassium azide) have been widely promoted as nematocides in soils carrying agricultural crops. The advantage is that they perform their nematocidal duty (often while the soil is covered with plastic tarps to confine the vapors and extend their active period) but then decompose and dissipate before the crops are harvested. The theory was that all the azide would have decomposed by the time the root vegetables (carrots) are harvested.

#### 1.1.3 Potassium Azide

Potassium azide,  $\text{KN}_3$ , CAS RN [20762-60-1],  $M = 81.1184 \text{ g/mol}$ , is in many of its properties similar to sodium azide. It can be used as a source of nitrogen in gas generants, but its nitrogen content is less than that of sodium azide (51.8 mass-% nitrogen as opposed to 64.6% in  $\text{NaN}_3$ ).

The thermal decomposition of potassium azide leads to the elements from which it was formed [69, 70]. The rate of decomposition of potassium azide was increased by several orders of magnitude by addition of transition metal salts [71].

When freshly crystallized potassium azide is irradiated with UV light, color centers (F-centers) are developed and the salt simultaneously decomposes with evolution of nitrogen and deposition of potassium in the lattice.

Potassium azide has been used as a pre-harvest nematocide to control worm pests in agricultural beet and carrot crops.

## 1.2 Other Metal Azides

Most metal azides are explosive and shock sensitive. Lead azide is (was) used as a stab-sensitive primary explosive in percussion caps in munitions. The accidental formation of metal azides from sodium azide in contact with metals or metal oxides has caused accidents.

Aluminum azide,  $\text{Al}(\text{N}_3)_3$ , has a very high nitrogen content, but it is explosive and very sensitive and it has been the cause of laboratory accidents during attempts at its preparation. Aluminum azide can be prepared by reaction of aluminum chloride with sodium azide in tetrahydrofuran solution [72] or by reaction of trimethylaluminum with hydrogen azide at low pressures [73].

## 2 Azides of Nitrogen Bases

Azides of nitrogen bases are of interest as high-nitrogen compounds for gas generators. This involves mainly ammonium azide,  $\text{NH}_4\text{N}_3$ , and hydrazinium azide,  $\text{N}_2\text{H}_5\text{N}_3$ ,  $\text{N}_2\text{H}_5\text{N}_3$ . They have been tested in the solid and liquid (dissolved in water or hydrazine) forms. We opted to list inorganic azides here immediately preceding organic azides. Hydrazinium azide is the compound with the highest nitrogen content (93 mass-%) and has been discussed in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers,” although it is not an oxidizer. Hydrazinium azide,  $\text{N}_2\text{H}_5\text{N}_3$ , is closely related to another hydronitrogen, ammonium azide,  $\text{NH}_4\text{N}_3$ , which is described here along with organic azides. This is not a very logical location for an ionic azide compound, such as ammonium azide, but it had to be either spliced in with ammonium salt oxidizers, such as ammonium nitrate (AN) or ammonium perchlorate (AP) or it could have been listed following the hydrazinium azide section.

The properties of azides of organic amines and amides are described in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines,” and chapter “Amides and Imides.” Guanidinium azide and triaminoguanidinium azide are relatively stable high-nitrogen compounds suitable as ingredients in gas generators.

## 2.1 Ammonium Azide

Ammonium azide, also known as ammonium trinitride, ammonium azoimide,  $\text{NH}_4\text{N}_3$ ,  $\text{N}_4\text{H}_4$ , CAS RN [12164-94-2],  $M = 60.059 \text{ g/mol}$ , is one of the few compounds that consists only of nitrogen and hydrogen. Thus, if it decomposes as constituents in gas generants, it does not leave a solid residue as the alkali metal azides would.

With a nitrogen content of 93.23 mass-%, ammonium azide is one of the best sources of nitrogen for gas generants. The exhaust of ammonium azide formulations with the proper oxidizer (e.g., AN) would be very clean since it contains only nitrogen and steam. Its oxygen balance is -53.28%, just enough oxygen is needed to combust the hydrogen in the ammonium ion to water. The main disadvantage of ammonium azide as a gas generant in any application is its high volatility and the toxicity of the ammonium azide vapors. Antiquated names at one time used for ammonium azide were ammonium trinitride or ammonium azoimide.

### 2.1.1 Preparation of Ammonium Azide

Ammonium azide can be prepared by mixing solutions of ammonium chloride and sodium azide in dimethylformamide at 373 K (100 °C). The solvent is then drawn off in a vacuum, but some of the volatile salt will be lost with the solvent. Owing to its high vapor pressure and toxicity, this compound has not yet found any practical applications.

Ammonium azide may be prepared by neutralization of hydrazoic acid in ether solution with gaseous ammonia or by metathetical reaction of dry sodium azide with ammonium nitrate at 473 K (a very hazardous operation) [74, 75].

Ammonium azide may be prepared by the reaction of ammonia and nitrous oxide over a hydrogenation catalyst at 783 K [76]

However, if the temperature conditions and the space velocity in the catalytic reactor are not chosen correctly, the ammonium azide formed would decompose and the reaction proceeds all the way to nitrogen and water, useless reaction products

This reaction can proceed with explosive power.

Ammonium azide solutions were prepared by ion exchange by first loading an anion exchange resin with azide ions from sodium azide, and then eluting the column with aqueous ammonia [77].

Traces of ammonium azide may be formed during the slow decomposition or photolysis of hydrazoic acid  $\text{HN}_3$ . If the decomposition products of hydrazoic acid are quenched on a cold finger, blue imine  $(\text{NH})_3$  will freeze out, but eventually decompose forming ammonium azide.

Ammonium azide can be prepared by reaction of trimethylsilyl azide with ammonium fluoride in methanol [78]

The same method can also be used for preparation of hydrazinium(1+) azide or hydroxylammonium azide.

#### 2.1.1.1 Synthesis of Other Hydronitrogens

It has been attempted to synthesize new hydronitrogen compounds ( $\text{NH}_5$ ?  $\text{N}_2\text{H}_6$ ?) by subjecting ammonium azide to extremely high pressures. At first, density functional theory calculations were performed to develop a new equation of state and to see which polymorphs might form if the salt is compressed to 3.3 GPa [79]. Novel polymorphs of  $\text{NH}_4\text{N}_3$  were found using a simple structure search algorithm employing random atomic displacements upon static compression.

A combined theoretical and experimental study of the high-pressure behavior of ammonium azide using density functional theory considered the relative thermodynamic stability of the material with respect to two other crystal phases, *trans*-tetrazene and  $(\text{NH})_4$  [80, 81]. Raman spectra of  $\text{NH}_4\text{N}_3$  were measured at pressures up to 71 GPa at room temperature. There was no evidence of a phase transition to either tetrazene or tetrazetidine  $(\text{NH})_4$ .

*Ab initio* molecular dynamics simulations predicted that ammonium azide should be an effective precursor to form polynitrogen [82]. Simulations at 60 and 90 GPa showed that the critical temperatures for nitrogen polymerization were about 2200 and 1600 K, respectively. Compared with molecular nitrogen (110 GPa and 2000 K), the synthesis pressure of polymeric nitrogen starting with ammonium azide should be significantly lower.

Ammonium azide is the thermodynamic ground state of  $\text{N}_4\text{H}_4$  compounds in preference to *trans*-tetrazene or poly-hydro-nitrogen  $(\text{NH})_\infty$ . Calculations predicted that ammonium azide undergoes a phase transition to *trans*-tetrazene at around ~39–43 GPa followed by *trans*-tetrazene to  $(\text{NH})_\infty$  at around 80–90 GPa in the temperature range 0–650 K [83]. The calculated pressure dependent IR spectra predicted that the N–H stretching frequencies should undergo red and blue shifts corresponding to strengthening and weakening of hydrogen bonding, respectively, below and above 4 GPa.

#### 2.1.1.2 Encapsulation of Ammonium Azide

Because ammonium azide has a relatively high vapor pressure at room temperature and sublimates easily, it has been attempted to reduce its volatility by encapsulating it with an impermeable barrier coating [84, 85]. Viton and nitrocellulose (NC) have been tested as coating agents. The best stabilized coated ammonium azide was made by using 4.5% of NC as coating, which increased the maximum sublimation temperature

by about 30 °C with respect to an uncoated sample. Similar coating methods may also be useful for encapsulating hydrazinium azide.

### 2.1.2 Physical Properties of Ammonium Azide

Ammonium azide forms colorless, non-hygroscopic crystals with a density of 1.346 g/cm<sup>3</sup> which start to sublime at 406–407 K (133–134 °C) and explode when heated to 433 K (160 °C). The main disadvantage of ammonium azide as a potential propellant or gas generant ingredient is the high volatility and its tendency to sublime even at moderate temperatures.

#### 2.1.2.1 Density of Ammonium Azide

The density of ammonium azide derived from crystallographic XRD data is 1.365 g/cm<sup>3</sup> [78].

#### 2.1.2.2 Vapor Pressure of Ammonium Azide

The vapor pressure of ammonium azide is summarized in Table 4.

**Table 4:** Vapor pressure of ammonium azide.

| Temperature |       |       | Vapor pressure |       |        |
|-------------|-------|-------|----------------|-------|--------|
| K           | °C    | °F    | millibar       | mm Hg | Pa     |
| 302.3       | 29.2  | 84.6  | 1.3            | 0.98  | 130    |
| 322.5       | 49.4  | 121   | 7              | 5.25  | 700    |
| 332.3       | 59.2  | 138.6 | 13             | 9.75  | 1300   |
| 342.5       | 69.4  | 157   | 27             | 20.3  | 2700   |
| 353.2       | 80.1  | 176.2 | 54             | 40.5  | 5400   |
| 359.8       | 86.7  | 188.1 | 80             | 60.0  | 8000   |
| 368.3       | 95.2  | 203.4 | 135            | 101   | 13500  |
| 380.8       | 107.7 | 225.9 | 260            | 195   | 26000  |
| 393.5       | 120.4 | 248.7 | 530            | 398   | 53000  |
| 406.9       | 133.8 | 272.8 | 1010           | 758   | 101000 |

Data source: [86]

The vapor pressure of ammonium azide can be calculated from the equation

$$\log P = +11.325 - (3428.6/T)$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

The kinetics of sublimation of ammonium azide have been investigated over the temperature range 360–389 K in a continuous flow of dry argon by TGA [87]. Sublimation follows zero-order kinetics with a corresponding activation energy of 93.3 kJ/mol,

which was slightly higher than its heat of sublimation (73.4 kJ/mol) determined from differential scanning calorimetric (DSC) cooling thermograms. It was suggested that ammonium azide undergoes molecular sublimation and that the vapor readily dissociates above 418 K into  $\text{NH}_3$  and  $\text{HN}_3$ . A heat of formation of 185.6 kJ/mol was deduced for gaseous  $\text{NH}_4\text{N}_3$ .

The solubility of ammonium azide in various solvents at 293 K is 20 g/100 mL water, 3.3 g/100 mL methanol, 1.06 g/100 mL ethanol and 0.006 g/100 mL ether.

### 2.1.2.3 Infrared Spectra of Ammonium Azide

Infrared spectra of solid ammonium azide at 68 K, prepared by sublimation onto a cold salt window, seem to indicate a disordered crystal which became ordered on warming above 150 K [88]. A band at  $1830\text{ cm}^{-1}$  was assigned as a combination involving a lattice torsional motion of the ammonium ion ( $420 \pm 20\text{ cm}^{-1}$ ). The vapor over ammonium azide at room temperature contained predominantly hydrazoic acid and ammonia.

The partial correlation field splitting of the symmetric stretching and bending  $\text{N}_3^-$  internal modes and the low frequency lattice modes in crystalline ammonium azide have been observed using far IR and laser Raman spectroscopy [89]. The vibrational modes were assigned by factor group analysis and compared with the neutron inelastic scattering spectrum of the salt.

High-pressure IR absorption and Raman scattering studies of ammonium azide at room temperature at pressures up to 20 and 22 GPa were done in search of a pressure-induced phase transition at 2.9 GPa [90]. All observed vibrational modes maintained their identities at the high-pressure phase, indicating that  $\text{NH}_4\text{N}_3$  was still present in the form of ammonium cations and azide anions linked by hydrogen bonds ( $\text{N}-\text{H}\cdots\text{N}$ ). Above 2.9 GPa, the relative magnitude of the torsional mode weakened, and the  $\text{N}-\text{H}$  symmetric stretch displayed a red shift, indicating strengthened hydrogen bonding energy. The opposite effects were observed above 12 GPa, where the relative magnitude of the torsional mode strengthened and the  $\text{N}-\text{H}$  symmetric stretch reverted to a blue shift, indicating weakened hydrogen bonding energy. The hydrogen bonding energy changes with an increase of pressure can be ascribed to a phase transition at 2.9 GPa and a rotational or bending behavior of azide ions at 12 GPa.

Absorptions in the IR spectrum of ammonium azide crystals in a KBr pellet were observed at 3144, 3012, 2834, 2036, 1818, 1418, 663, 651, and  $626\text{ cm}^{-1}$  [78].

### 2.1.2.4 Crystal Structure of Ammonium Azide

The unit cell dimensions of orthorhombic ammonium azide crystals with four molecules to the unit cell were determined from XRD data as  $a = 8.930 \pm 0.003\text{ \AA}$ ,  $b = 8.642 \pm 0.003\text{ \AA}$ ,  $c = 3.800 \pm 0.002\text{ \AA}$  with a space group assumed to be  $Pmna$  or  $D_{2h}^7$  [91]. The crystal density was  $1.352\text{ g/cm}^3$ .

Another XRD measurement of orthorhombic ammonium azide crystals with space group  $Pmna$ , gave  $a = 8.948\text{ \AA}$ ,  $b = 3.808(2)\text{ \AA}$ ,  $c = 8.659(3)\text{ \AA}$ ,  $Z = 4$ ,  $D_c = 1.352\text{ g/cm}^3$ , and

$D_m = 1.352 \text{ g/cm}^3$  [92]. The corrected N—N distance was  $1.186(4) \text{ \AA}$  in both azide groups. There were two strong hydrogen bonds, with N—N distances of  $2.975(4)$  and  $2.967(3) \text{ \AA}$ .

Pressure-dependent Raman spectroscopy studies revealed a polymorph phase transition in simple molecular ionic crystal  $\text{NH}_4\text{N}_3$  at a pressure of  $\approx 3 \text{ GPa}$  which had not been predicted by *ab initio* calculations [93]. Hydrogen bonding was spectroscopically evident in both low-pressure and high-pressure phases. The strength of hydrogen bonds appeared to change at the phase transition: in the low-pressure phase  $\text{NH}_4\text{N}_3$  behaved as a system with very strong hydrogen bonding whereas changes of spectra with pressure in the high-pressure phase were indicative of weak or medium-strength hydrogen bonds. The high-pressure phase is most likely thermodynamically stable up to pressures of  $\approx 55 \text{ GPa}$ , contradicting the *ab initio* studies predicting transformation of  $\text{NH}_4\text{N}_3$  to non-molecular hydronitrogen solid at  $36 \text{ GPa}$ . Polymorph phase transition was observed in  $\text{NH}_4\text{N}_3$  at  $\approx 3 \text{ GPa}$  by pressure-dependent Raman studies. The strength of hydrogen bonds appeared to change at the phase transition as illustrated by dependence of N—H stretching frequency on pressure.

A computational study of the structural, electronic, bonding and optical properties of orthorhombic ammonium azide has been performed using a plane wave pseudopotential method based on density functional theory (DFT) [94].

The peculiar behavior of the symmetric stretch of the  $\text{N}_3^-$  anion and the bending mode of the  $\text{NH}_4^+$  cation in the high-pressure phase II (above  $3 \text{ GPa}$ ) of the molecular ionic crystal  $\text{NH}_4\text{N}_3$  were studied by pressure-dependent Raman spectroscopy up to a pressure of  $20 \text{ GPa}$  [95]. The spectra in the pressure range above  $10 \text{ GPa}$  revealed a remarkable intensity transfer between bands and a level repulsion (characteristic of vibrational resonance coupling) that is mediated by hydrogen bonding between the  $\text{N}_3^-$  and  $\text{NH}_4^+$  ions.

The structural, elastic, mechanical, electronic properties, formation energy and cohesive energy of orthorhombic  $\text{NH}_4\text{N}_3$  and monoclinic  $\text{N}_2\text{H}_5\text{N}_3$  were studied by a plane wave method based on the first-principles density functional theory [96]. The orthorhombic  $\text{NH}_4\text{N}_3$  crystal is more energetically stable. The independent elastic constants, bulk modulus, shear modulus, Young's modulus and Poisson's ratio of two compounds were then investigated. The electronic band structures, density of states, and charge density distributions of orthorhombic  $\text{NH}_4\text{N}_3$  and monoclinic  $\text{N}_2\text{H}_5\text{N}_3$  were analyzed to better understand electronic properties and chemical bonding in these two molecules.

The crystal structure of ammonium azide has been studied by *in situ* high-pressure XRD and Raman scattering at room temperature [97]. Ammonium azide exhibits strong hydrogen bonding features with compression. The hydrogen bonds weaken with increasing pressure due to the bending of N—H $\cdots$ N bond, leading to an increase of N—H stretch frequency and rotation of azide anions up to  $2.9 \text{ GPa}$ . The orientation of azide anions influences the compressibility properties of ammonium azide. The phase tran-

sition involves rotation of azide anions and a proximity of *a* and *c*, preliminarily assigned as a reversible second-order orthorhombic to tetragonal transition.

The pressure-induced phase transitions in hydronitrogen compounds were investigated using first-principles density functional theory [98, 99]. The tetragonal structure with space group  $P4_2/n$  is mechanically stable and ductile. The thermodynamic stability decreased in the order  $Pmna > P\bar{1} > P4_2/n > P2_1/m$ . With increasing pressure, the phase transition pressures of transitions  $Pmna \rightarrow P4_2/n$ ,  $P4_2/n \rightarrow Pmna$ ,  $Pmna \rightarrow P\bar{1}$ , and  $P\bar{1} \rightarrow P2_1/m$  are 5.6, 15.0, 30.0, and 69.2 GPa, respectively, which are in agreement with the available data.

The structural parameters of orthorhombic ammonium azide crystals with a space group of  $Pmna$  obtained by crystallographic XRD measurements are  $a = 8.9331(10) \text{ \AA}$ ,  $b = 3.7824(4) \text{ \AA}$ ,  $c = 8.6519(10) \text{ \AA}$ ,  $\alpha = \beta = \gamma = 90^\circ$ ,  $Z = 2$  [78]. The calculated crystal density was  $1.365 \text{ g/cm}^3$ .

### 2.1.2.5 Thermodynamic Properties of Ammonium Azide

The literature gives several values of the enthalpy of formation of  $\text{NH}_4\text{N}_3$ , ranging from 20.2 to 27.6 kcal/mol. An analysis of the original sources showed that the values of the enthalpy of formation equal to 20.4 and 20.2 kcal/mol are erroneous, since uncorrected data were used. Values of 26.4–26.79 kcal/mol were regarded as the most reliable.

The standard enthalpy of formation of ammonium azide is  $+1922.8 \text{ kJ/kg} = +115.5 \text{ kJ/mol} = +459.6 \text{ kcal/kg} = +27.6 \text{ kcal/mol}$  [86]. The enthalpy of formation is a very high positive number, indicating that this is an energetic chemical that can be used as a solid propellant ingredient, nitrogen gas generant and clean exhaust explosive (if other detrimental properties do not prevent us from doing that).

The standard molar enthalpy of formation of ammonium azide at 298.15 K has been derived from measurements of the energy of combustion in oxygen as  $\Delta H_f(\text{cr}) = 114.14 \pm 0.94 \text{ kJ/mol} = +27.28 \pm 0.22 \text{ kcal/mol}$  [100].

### 2.1.3 Chemical Properties of Ammonium Azide

Ammonium azide is soluble in liquid ammonia and on evaporation of the solvent forms ammonates containing one or more molecules of ammonia as solvated ammonia of crystallization. The diammonate  $\text{NH}_4\text{N}_3 \cdot 2\text{NH}_3$  forms clear, colorless elongated plates stable at 240 K ( $-33^\circ\text{C}$ ) but decomposes at 273 K ( $0^\circ\text{C}$ ).

Another high-nitrogen azide, hydroxylammonium azide has not received much attention. It appears to be just as unstable as ammonium azide or hydrazinium azide.

Ammonium azide sublimes below 523 K ( $250^\circ\text{C}$ ) at 1.3–20 kPa (10–150 mm Hg), and slowly decomposes between 523–583 K ( $250$ – $310^\circ\text{C}$ ) at 20 kPa (150 mm Hg). Ammonium azide vaporizes and dissociates into  $\text{NH}_3$  and  $\text{HN}_3$  and then the  $\text{HN}_3$  explodes.

### 2.1.4 Strand Burning of Ammonium Azide

The steady-state combustion of  $\text{NH}_4\text{N}_3$  and  $\text{N}_2\text{H}_5\text{N}_3$  was studied in a windowed constant-pressure bomb at 0.1–36 MPa [101]. The  $\text{N}_2\text{H}_5\text{N}_3$  burned 3–4 times faster than  $\text{NH}_4\text{N}_3$  over this pressure range. The combustion temperature of both compounds was 240–430 K higher than the temperature calculated for the thermodynamic equilibrium composition of the combustion products due to the presence of large amounts of undissociated  $\text{NH}_3$  (0.97 and 0.87 mol-% per mol of  $\text{NH}_4\text{N}_3$  and  $\text{N}_2\text{H}_5\text{N}_3$ , respectively). The reaction at the combustion surface was the dissociation of the salts into  $\text{HN}_3$  and the parent base. The increase in surface temperature with pressure was dependent on the dissociation enthalpy of the salts, and the combustion rate was dependent on the gas-phase heat release. The main energy release mechanism is the decomposition of  $\text{HN}_3$ . Kinetics of  $\text{HN}_3$  gas-phase decomposition can be expressed as  $k = 10^{16.26} \exp(-19350/T) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ . For comparison, the combustion rate of liquid  $\text{HN}_3$  at 0.1 MPa is  $1.9 \text{ g cm}^{-2} \text{ s}^{-1}$ .

### 2.1.5 Safety Properties of Ammonium Azide

The critical diameter of  $\text{NH}_4\text{N}_3$  was determined in cellophane or thin-walled glass shells [102]. The critical diameter of  $\text{NH}_4\text{N}_3$  detonations as a function of packing density rises sharply with the bulk density (Figure 1).

**Figure 1:** Critical diameter of  $\text{NH}_4\text{N}_3$  detonations as a function of packing density (reprinted and modified from [102], by permission from ©1977 Springer Nature; permission conveyed through Copyright Clearance Center, Inc.)

The detonation velocity of  $\text{NH}_4\text{N}_3$  confined in steel tubes as a function of packing density and sample geometry goes through a maximum at  $0.7 \text{ g/cm}^3$  (Figure 2). The solid line is a linear curve fit for the range  $\rho = 0.4 - 0.7 \text{ g/cm}^3$  based on the equation  $D = 1.1 + 3.1 \times \rho \text{ km/s}$ .

**Figure 2:** Detonation velocity of  $\text{NH}_4\text{N}_3$  detonations as a function of packing density (reprinted and modified from [102], by permission from ©1977 Springer Nature; permission conveyed through Copyright Clearance Center, Inc.)

Theoretical calculations based on the enthalpy of formation predict a detonation velocity of 6.45 km/s and a detonation pressure about 15.16 GPa computed by Kamlet-Jacobs empirical equations [94].

### 2.1.6 Applications of Ammonium Azide

Ammonium azide has been proposed as the key ingredient for gas generant formulations where its advantage over sodium azide would be that it does not leave a solid residue, but its volatility prevents its actual use in practical systems [103].

Ammonium azide has been used as the starting material in the high-pressure synthesis of other hydronitrogens, subjecting it to very high pressures, where phase changes occur, and the atoms rearrange themselves [83].

## 2.2 Hydrazinium Azide

Hydrazinium azide (HA) is one of the compounds with the highest nitrogen content (93%) and has received considerable attention as a source of nitrogen gas in gas generators. Hydrazinium azide solutions in hydrazine have been evaluated as monopropellants (see *Encyclopedia of Monopropellants*, chapter “Hydrazine Monopropellants”).

There are two Chemical Abstract Service Registry Numbers for hydrazinium azide: [38551-29-0] and [14662-04-5]. It is not known which is the correct (preferred) one.

There is a different CAS RN for hydrazinium(1+) azide hydrazinate which is [14546-45-3].

The preparation and physical properties of hydrazinium azide were already discussed in *Encyclopedia of Oxidizers*, chapter “Hydrazinium Salt Oxidizers,” along with other hydrazinium salts that are potential oxidizers. Hydrazinium azide is not an oxidizer, so it somewhat violated the ground rules for selecting chapter titles and contents in this book for oxidizers and fuels when hydrazinium azide was discussed under oxidizers instead of fuels. It would have made sense to discuss both ammonium azide and hydrazinium azide here in this chapter next to each other because the two salts are very similar in their chemical composition and behavior.

### 2.3 Decomposition of Inorganic Azides

In ionic inorganic azide compounds, the lengths of N—N bonds are the same (the polarization of azido group is not a consideration). N—N bonds are not broken in the decomposition, which follows equations like:

where M is an alkali metal.

## 3 Organic Azido Compounds

The azide group as a ligand in an organic compound is called the azido group. The “o” at the end of this term puts it in the same category with nitro, amino or nitramino groups. Sometimes it is also called the triazo group. Azido compounds are derivatives of hydrazoic acid (HN<sub>3</sub>) where the hydrogen is replaced by an alkyl or aryl group. The bond between the azido group and its organic skeleton is a covalent bond. The azido group attached to an organic carbon-carbon backbone makes fuels with higher enthalpy of formation and higher nitrogen content, both attractive for better rocket propellants and better gas generants. The azido group is an explosivesophoric group. So, if one lonely azido group attached to an organic compound does not yet give the desired specific impulse, one is inclined to try two, three or more azido groups attached to the same molecule. Unfortunately, there is a limit as to how many azido groups can be attached to a molecule before the compound becomes prohibitively unstable. Several compounds described in the current chapter may fall into that category. Nevertheless, these polyazido compounds were prepared and studied and described here in order to

find out where the limit of stability is. The other question is about the effect of neighboring groups like  $-\text{NO}_2$ ,  $-\text{CN}$  or  $-\text{NH}_2$  on the stability of alkyl azides.

Although liquid azides discussed here have not found the same wide range of applications in rocket propellants and gas generants as solid azides, they are discussed here in detail because some of the same synthesis methods can be used for solid, polymeric azides and some of the monomers are liquids before they are polymerized.

Polymeric azides as binders for solid propellants will be discussed in future volumes on solid propellants. Those discussions center around the use of glycidyl azide polymers (GAP) as binders in solid rocket propellants. Of all organic azido compounds, GAP is the only one that has found practical application and it is still actively being investigated in many new propellant formulations. Attaching allyl  $\text{H}_2\text{C}=\text{CH}-\text{CH}_2-$  groups to organic azides makes them suitable as monomers for polymerization and use as energetic binders [104].

Azides of heterocyclic ring structures, such as 3-azidooxetane or triazido-s-triazine, are discussed in *Encyclopedia of Liquid Fuels*, chapter "Heterocyclic Amines." Here we are summarizing only organic azido compounds that are neither polymers nor amines. The preceding section already described inorganic azides.

There are many publications on organic azides which may be useful as an introduction to this exciting group of chemicals [105–114]. Exciting because many of these compounds are thermally unstable or shock sensitive or both and may cause accidental explosions when they are least expected. The Patai book contains several chapters of interest for the synthesis and applications of azido compounds [105]. The book "Science of Synthesis: Houben-Weyl Methods of Molecular Transformations (former Methods in Organic Chemistry)" in volume 41 contains information on nitro, nitroso, azo, azoxy, and diazonium compounds, azides, triazenes, and tetrazenes [115].

A good, but now obsolete survey of alkyl and aryl azides was published in 1954 [116]. It should be updated. Another review covers decomposition and addition reactions of organic azides [117].

Other azido compounds have already been discussed under amines (CINCH, DMAZ) because the central skeleton of the molecule was an amine and the azido groups were only attached as explosophoric paraphernalia. Dimethylaminoethyl azide (DMAZ) has received much attention among all organic liquid azides both as a fuel (*Encyclopedia of Liquid Fuels*, chapter "Aliphatic Amines") and as a monopropellant. There is some overlap between these two sections. Compounds discussed here contain nitrogen only as part of the azido (or a nitro) group, but not as part of the skeleton of the molecule. The skeleton of the azido compounds discussed here is a carbon skeleton without any hetero-atoms. In many cases azido groups have been combined with other explosophoric groups, mostly nitro and nitroxy groups, in the quest for more energetic compounds.

There are hundreds of publications and patents on azide compounds in rocket propellants and a complete summary of all those references would fill an entire book in its own right. In the current section we can give only a superficial, introductory re-

view and include some typical applications. A new book on liquid explosives contains a chapter on azido compounds as liquid explosives [118]. Azides are physiologically active and have medicinal therapeutic uses, mainly for blood pressure lowering [119].

Organic azides have assumed an important position as building blocks for syntheses at the interface between chemistry, biology, medicine and materials science. They can be used in cycloadditions, aza ylide chemistry and the synthesis of a variety of heterocyclic compounds, as described in several summaries of the preparation and uses of organic azides [120, 121]. Another multi-author compendium on organic azides contains 16 chapters, including one on azides as energetic materials [122]. See also [123].

Azido compounds evaluated as energetic plasticizers include bis(1,3-diazo-2-propyl) formal,  $[(N_3CH_2)_2CHO]_2CH_2$ ,  $C_4H_7N_6O_2$ , BDPP [124], 1,5-diazo-3-nitrazapentane,  $N_3CH_2CH_2N(NO_2)CH_2CH_2N_3$ ,  $C_4H_8N_8O_2$ , DIANP [125], 1,1,1-tris-(azidomethyl)ethane,  $(N_3CH_2)_3CCH_3$  [126], and many others [127].

Various azido compounds, including azidonitramine, *N*-nitro-*N*-azidomethyl-gemdinitroethyl methylamine, *N,N*-bis(azidomethyl-*gem*-dinitroethyl)-ethylenedinitramine, azido nitro compounds, 2-nitro-2-methyl-1,3-diazidopropane, 2-nitro-2-azidomethyl-1,3-diazidopropane, and tetraazidomethyleneethane, pentaerythritol diazido dinitrate were evaluated as energetic additives for rocket propellants [128].

Azido compounds of high energy materials interest are bis(azidomethyl)oxetane, azidomethyl methyl oxetane, 1,3-diazo-2-nitrazapropane (DANP), 1,5-diazo-2,4-dinitrazapentane (DADZP), 1,7-diazo-2,4,6-trinitrazaheptane (DATH), and *n*-propyl azidoethyl nitramine [129].

Many organic azides have been tested as burning rate increasing additives for hydrocarbon fuels in turbojet or ramjet engines, where microexplosions cause fuel droplets to shatter into many small droplets that burn faster than the large droplets.

### 3.1 Preparation of Organic Azides

The simplest method for synthesis of alkyl azides is the reaction of alkyl halogenides with sodium azide:

where X = Cl, Br, or I. This can be done in aqueous solution or in aprotic solvents. An improved method for the synthesis of alkyl azides used 2-(2-ethoxyethoxy)ethanol, also known under the trade name Carbitol, as the solvent [130].

A series of monoazidoalkanes and diazidoalkanes were prepared to compare the molecular structure of these compounds with their impact sensitivity [131]. All monoazidoalkanes were insensitive to impact. The diazidoalkanes gave varying results, depending on the structure. See also [120, 132, 133].

Methyl azide has been found as an unwanted reaction product in the incomplete reaction of dinitrogen tetroxide and methylhydrazine, which ordinarily would lead to hypergolic ignition. Very short pulses of bipropellant thrusters may result in incomplete combustion and accumulation of intermediates, such as methylhydrazine (MMH) nitrate or methyl azide. Accumulation of methyl azide as a product of incomplete reaction of dinitrogen tetroxide (NTO) and MMH could lead to explosions.

A series of alkyl azides and diazides in quantities of 100–200 g were synthesized and characterized by IR and NMR spectra, including 1-azidobutane, CAS RN [7332-00-5P], 1-azidopentane, CAS RN [26330-06-3], 1-azidohexane, CAS RN [6926-45-0], 1-azidoheptane, CAS RN [44961-22-0], and 1-azidooctane, CAS RN [7438-05-3] [134]. The report gives some spectra but lacks physical properties of the prepared compounds. A new method for preparation of vicinal diazides starting with alkenes was developed and used for the synthesis of 1,2-diazidocyclopentane and 1,2-diazidocyclohexane.

### 3.2 Physical Properties of Organic Azides

The simplest alkyl azide, methyl azide, azidomethane,  $\text{CH}_3\text{N}_3$ , CAS RN [624-90-8] boils at near room temperature at 293–294 K. It is unstable and its vapor and liquid is detonable, in particular in the presence of mercury [135]. Ethyl azide, azidoethane,  $\text{C}_2\text{H}_5\text{N}_3$ , CAS RN [871-31-8] boils at 322 K (49 °C) and its vapors are also detonable.

#### 3.2.1 Melting Points of Organic Azides

It is difficult to determine the melting points of organic azides because they may decompose or explode before they melt. Three correlations for the prediction of melting point of different types of organic azides containing alkyl azides, alkenyl azides, aryl azides, acyl azides, and heteroazide compounds were based on the elemental composition as additive parameter and the contribution of some specific polar groups/structural moieties as non-additive functions [136]. These correlations have been used for 259 different organic azide compounds, including complex molecular structures. The models were validated by internal and external validation tests where their applicability domains were defined and analyzed.

A similar method was used for prediction of melting points of organic peroxides, organic azides, organic nitrates, polynitro arenes, polynitro heteroarenes, acyclic, and cyclic nitramines, nitrate esters, and nitroaliphatic compounds [137].

#### 3.2.2 Boiling Points of Organic Azides

Table 5 contains CAS RN numbers, normal boiling points and data for the ultraviolet spectra in 95% EtOH for several alkyl and cycloalkyl azides. A comparison of the normal boiling points of alkyl azides and cycloalkyl azides showed that the boiling points of cycloalkyl azides were slightly higher than those of straight chain alkyl azides with

same number of carbon atoms [138]. The mean molar refraction value of the azido group was calculated to be about 9.4 in alkyl azides and 10.2 in the case of aryl azides.

**Table 5:** Boiling points and UV absorption of alkyl and cycloalkyl azides.

| Compound name          | Formula                                       | CAS RN      | Boiling point      |                  | UV absorption         |                           |
|------------------------|-----------------------------------------------|-------------|--------------------|------------------|-----------------------|---------------------------|
|                        |                                               |             | K                  | °C               | $\lambda_{\max}$ , nm | $\epsilon \times 10^{-3}$ |

### 3.2.3 Vapor Pressure of Organic Azides

The vapor pressures of a group of alkyl azides have been experimentally determined by accurately measuring vapor pressure as a function of temperature and then correlating the data with the Clausius-Clapeyron relation [139]. The experimental procedure involved heating 10–15 mL of the test liquid in a two-neck, round-bottom flask immersed in a silicone oil bath that is stable to temperature variations and can be heated up to 573 K (300 °C). The test vapor-liquid temperature was measured with a thermocouple placed immediately above the liquid interface, where saturated conditions were best observed. To minimize evaporative loss and maintain saturation conditions within the system, a condenser was used to recover vaporized liquid. Magnetically driven stirring bars were used to circulate both the test liquid and silicone oil bath to ensure temperature uniformity. A typical datum point was collected by first fixing the system pressure and then slowly raising the system temperature until the state of steady boiling was attained. The boiling points and latent heats of vaporization for the monoazides and diazides are compiled in Table 6. Overall, the boiling points of alkyl azides were higher than those of their alkane parent compounds. It is not clear if all those azides were *n*-azides with the azide group(s) in the terminal position(s) of the carbon chain, but that is the most likely assumption.

Table 6: Physical and thermodynamic properties of alkyl azides.

| Parent compound | Formula                                                       | Mol. mass | Density $\rho$    | Boiling point | Heat of evaporation |          | Enthalpy of formation, vapor, at 298 K |          | Heat of combustion at 298 K |          | Heat of decomposition |          |
|-----------------|---------------------------------------------------------------|-----------|-------------------|---------------|---------------------|----------|----------------------------------------|----------|-----------------------------|----------|-----------------------|----------|
|                 |                                                               |           |                   |               | at 298 K            | at 298 K | at 298 K                               | at 298 K | at 298 K                    | at 298 K | at 298 K              | at 298 K |
|                 |                                                               | g/mol     | g/cm <sup>3</sup> | K             | °C                  | kJ/mol   | kJ/mol                                 | kcal/mol | kJ/mol                      | kcal/mol | l/g                   | cal/g    |
| Monoazides      |                                                               |           |                   |               |                     |          |                                        |          |                             |          |                       |          |

Data source: [139]

Figures 3 and 4 show the vapor pressures of several alkyl azides and diazides. Vapor pressures of 23 organic azides have been determined by the transpiration method and the molar enthalpies of vaporization  $\Delta H_{\text{vap}}$  of these compounds were derived from the temperature dependencies of vapor pressures [140]. The results are summarized in Table 7.

**Figure 4:** Vapor pressures of several alkyl diazides (reprinted and modified from [139], with permission from ©1989 Elsevier; permission conveyed through RightsLink.)

### 3.2.4 Infrared Spectra of Organic Azides

Not all compounds for which IR spectra are reported in this section are suitable as rocket propellants. The main reason these compounds were studied, and the results are discussed here in substantial detail, was to have a tool for characterizing the molecular structure of azides and develop correlations between molecular structure, thermal stability, and energy content. Thermal stability and energy content of these molecules are important properties when these compounds are to be used as rocket propellants. It was also important to identify resonance interaction of azide  $\text{N}=\text{N}$  with conjugated  $\text{C}=\text{C}$  bonds in the alkylene groups. Would it stabilize or destabilize the molecule? Of course, IR spectra can also be used for purity and quality control of azides that are used as propellant ingredients.

A number of organic monoazides, with the general formula  $\text{RN}_3$ , were synthesized in which  $R$  was: (1) a saturated alkyl group, e.g.  $\text{CH}_3$ ,  $\text{C}_2\text{H}_5$ ,  $n$ -propyl azide,  $n\text{-C}_3\text{H}_7$  CAS RN [22293-25-0P]; (2) an olefinic group, e.g., allyl, butadienyl; or (3) an acetylenic group, e.g. azidoacetonitrile,  $\text{N}\equiv\text{CCH}_2$ , CAS RN [57707-64-9P], 3-azidopropyne,  $\text{HC}\equiv\text{CCH}_2$ , CAS RN [14989-89-0P],  $\text{MeC}\equiv\text{CCH}_2$  and their IR spectra were measured [141]. In addition, two diazides with unsaturated alkenyl and alkynyl groups were made for comparison: 2,3-diazido-1,3-butadiene,  $\text{H}_2\text{C}=\text{C}(\text{N}_3)\text{C}(\text{N}_3)=\text{CH}_2$ , CAS RN [91686-86-1P], and 1,4-diazido-2-butyne,  $\text{N}_3\text{CH}_2\text{C}\equiv\text{CCH}_2\text{N}_3$ , CAS RN [91686-83-8P]. The compounds (most of them very explosive) were studied by IR and Raman spectroscopy in liquid, in solution, and in the solid state, and by matrix isolation technique in IR. The spectra were interpreted in terms of one or in some cases two or more conformers and assigned with the aid of normal coordinate analysis. UV photolysis experiments in frozen nitrogen matrices at 12K were carried out and the reactions monitored by Fourier transform infrared (FTIR) spectroscopy. The intermediate products could in some cases be identified as imines. Six of the azides were investigated by gaseous electron diffraction and the molecular structures established.

Fully optimized geometries were calculated for hydrazoic acid, azidomethane, azidoethane, azidoethene, and azidomethanal and compared with existing experimental data [142]. Azidoethane exists in two conformations, *gauche* ( $71^\circ$ ) and *anti*, with an energy difference of 0.26 kJ/mol. Azidoethene and azidomethanal both prefer the *syn* orientation of the azide group with respect to the  $\text{C}=\text{C}$  or  $\text{C}=\text{O}$  bonds, the computed energy difference between the *anti* and *syn* conformation being 3.31 and 30.3 kJ/mol, respectively. The barrier to rotation around the  $\text{C}-\text{N}$  bond is 3.75 kJ/mol in azidomethane while in azidoethane it is 3.30 and 9.40 kJ/mol in the eclipsed anticlinal ( $120^\circ$ ) and *syn* positions, respectively. IR vapor phase absorption intensities were calculated, and theoretical spectra were presented for azidomethane and azidoethane.

Azidoacetonitrile, azidoethanenitrile,  $\text{N}\equiv\text{CCH}_2\text{N}_3$ , CAS RN [57707-64-9P] has been synthesized and the structure determined by electron diffraction from the vapor [143]. The substance slowly polymerized when kept at 243 K ( $-30^\circ\text{C}$ ) but appeared other-

wise to be considerably more stable than the isoelectronic 3-azidopropyne. IR spectra have been recorded of the vapor, liquid, solutions, solid at 90 K and of the molecule trapped in argon and nitrogen matrices at 15 K and absorption bands were assigned to molecular vibrations. Raman spectra of the cooled liquid and of the amorphous and crystalline solids were also obtained and assigned. The electron diffraction results showed the conformation to be *gauche* around the C—N bond with a dihedral angle of  $\alpha = 52^\circ(5)$  from *syn* and the NNN angle  $\alpha = 173^\circ(3)$  oriented *anti* to the C—N bond. The following bond distances ( $r_a$ ) between the heavy atoms were obtained:  $rC\equiv N = 115.4(5)\text{pm}$ ,  $rC-C = 146.5(15)\text{pm}$ ,  $rC-N = 147.5(6)\text{pm}$ ,  $rN=N = 124.5(5)\text{pm}$  and  $rN\equiv N = 113.5(4)\text{pm}$ . Note:  $1\text{pm} = 0.01\text{\AA}$ . Very large changes in both frequency and intensity have been observed in the vibrational spectra upon crystallization which may be due to intermolecular associations formed by the azido group but which can also be explained by a change of the molecular conformation from only *gauche* in the vapor and liquid phases to *anti* in the crystal phase.

3-Azidopropene, allyl azide,  $H_2C=CH-CH_2-N_3$ , CAS RN [821-13-6], was synthesized and its structure and conformational composition studied by electron diffraction from the vapor, IR spectra of the vapor, of the liquid and of the amorphous solid at 90 K, and Raman spectra of the cooled liquid and of the amorphous and crystalline solids at 90 K [144]. Analysis of the electron diffraction data revealed a multiplicity of indistinguishable solutions to the conformational composition consisting of variable amounts of the three conformers SG, GG, and GG', the letters referring to the *syn* or *gauche* conformation around the C—C and C—N bonds, respectively. The normal modes of vibration for the five distinct conformations of 3-azidopropene are calculated using transferred scaled quantum mechanical force fields for propene and azidoethane.

A safe method for the synthesis of azidoethane (ethyl azide,  $C_2H_5N_3$ ) starts with ethyl bromide [145].  $^1H$  and  $^{13}C$  nuclear magnetic resonance (NMR), IR, and Raman spectra of azidoethane in the region  $4000-40\text{cm}^{-1}$  have been recorded and interpreted in terms of two conformers, *anti* and *gauche*, present in the vapor and in the liquid, and of the *gauche* conformer in the crystalline solid (Figure 5). The enthalpy difference between the conformers, and the barrier to rotational isomerism in the nitrogen and argon matrixes were calculated. Raman studies of the liquid at 140–290 K revealed the *gauche* conformation to be the more stable in the liquid phase as well.

This series of spectroscopic work helped to understand the relationship between molecular structure and thermal stability of alkyl azides and in the future it would help in the synthesis of more stable azides that can be used as propellant ingredients.

### 3.2.5 Thermodynamic Properties of Organic Azides

Through either direct measurement or group additivity calculations, the densities, normal boiling points, latent heats of vaporization, limits of superheating, enthalpies of formation, combustion and decomposition, and adiabatic flame temperatures

have been approximately determined for the monosubstituted and disubstituted alkyl azides, which exhibit significantly enhanced droplet gasification rates and microexplosion events [139]. Similar determinations were also performed for some alkyl halides because their properties are like those of the organic azides.

The enthalpy of formation of  $\text{CH}_3\text{N}_3(\text{G})$  was predicted to be  $304.6 \pm 4 \text{ kJ/mol}$  ( $72.8 \pm 1 \text{ kcal/mol}$ ) at 298 K based on the agreement between the calculated and experimental values for  $\Delta H_f$  for  $\text{HN}_3$  [146].

The heats of vaporization of several azides determined by vapor pressure measurements by a transference method are summarized in Table 7. A correlation was sought between the heat of vaporization of alkyl monoazides and alkyl diazides and the number of carbon atoms in the alkyl chain [140].

**Table 7:** Heat of vaporization of organic azides.

| Compound name                | CAS RN      | Temp. range of measured data | $\Delta H_{\text{vap}}$ at 298.15 K, kJ/mol |
|------------------------------|-------------|------------------------------|---------------------------------------------|
| Azidocyclopentane(L)         | 33670-50-7  | 275–333                      | $41.3 \pm 0.4$                              |
| Azidocyclohexane(L)          | 19573-22-9  | 280–303                      | $49.2 \pm 0.5$                              |

Data source: [140]

Theoretical gas-phase enthalpies of formation of 29 azides were calculated by combining G4 theory calculations with an isodesmic reaction approach [147]. The internal consistency over a set of  $\Delta H_f^{\circ, 298}$  values was achieved by sequential adjustment of their values through the isodesmic reactions. Hydrogen azide,  $\text{HN}_3$ , was chosen as a key reference compound. Of the experimental data available for 16 compounds, predictive values agreed well with only 9 of them, while deviations of 25–55 kJ/mol were observed for 7 other compounds due to systematic errors in the experimental data for phenyl azide, 2-azidoethanol, azidocyclopentane, azidocyclohexane, 3-azido-

3-ethylpentane, 2-azido-2-phenylpropane and 1-azidoadamantane. The predicted gas-phase enthalpy of formation of 2-azidoethanol,  $\text{HOCH}_2\text{CH}_2\text{N}_3$ , ranged from +112.5 to +117.6 kJ/mol with an average of 114.7 kJ/mol.

1-Octyl azide,  $\text{C}_8\text{H}_{17}\text{N}_3$ , CAS RN [7438-05-3] and 1-decyl azide,  $\text{C}_{10}\text{H}_{21}\text{N}_3$ , CAS RN [62103-13-3] were prepared by reaction of the alkyl bromides with sodium azide and their heats of combustion measured in a combustion calorimeter [148]. The enthalpies of formation derived from the heats of combustion were  $+80.6 \pm 2.2$  kJ/mol for liquid octyl azide and  $+29.0 \pm 3.0$  kJ/mol for liquid decyl azide. The heats of vaporization of these compounds were measured by a vapor pressure method.

The measured enthalpy of formation of azidocyclohexane,  $\text{C}_6\text{H}_{11}\text{N}_3$ , CAS RN [19573-22-9] liquid was +108.4 kJ/mol while the predicted enthalpy of formation was +137.7 kJ/mol with a deviation of 29.3 kJ/mol [149]. The enthalpy of formation of azidocyclohexane vapor is +208 kJ/mol.

### 3.2.6 Molecular Structure of Organic Azides

*Ab initio* calculations of the structures of a group of organic  $\text{C}_1\text{--C}_4$  alkyl azides  $\text{RN}_3$  were carried out in comparison to hydrazoic acid  $\text{HN}_3$  [150]. Fully optimized geometries of all rotational conformers of these molecules were calculated. *Ab initio* MP2 analytical force fields were computed and the theoretical predicted vibrational wave numbers were compared to measured data. Good agreement was found between the theoretical and experimental IR/Raman and microwave spectra, and for structures obtained by electron diffraction. *Ab initio* calculations of organic alkyl azides revealed that they can exist as several rotational isomers. Raman spectroscopy and electron diffraction studies suggested that ethyl azide consists of two conformers: *gauche* with a dihedral angle of  $65^\circ$  and *anti* with a dihedral angle of  $180^\circ$  (Figure 5).

The calculated energy difference between the two conformers is only 0.59 kJ/mol, the *gauche* conformer being the more stable one. According to these studies, the following azides exist only as one conformer: 3-azidopropyne: *gauche*, azidoacetonitrile: *gauche*, 1-azido-2-butyne: *gauche*, 2-azido-1,3-butadiene: *trans*, *sym*. *Ab initio* calcu-

Figure 5: Molecular structures of ethyl azide.

lated relative stabilities were in full agreement with the experimental data, except for azidoacetonitrile. Allyl azide can exist as five distinct conformers.

The molecular structure of *tert*-butyl azide has been determined by gas-phase electron diffraction and quantum chemical calculations [151]. The calculations yielded near  $C_s$  symmetry for the *tert*-butyl group, *anti* conformation of the (C)N—N bond with respect to one of the (N)C—C(H3) bonds, and an essentially free rotation around the (C)N—N(N) bond with a 0.34 kcal/mol energy difference between *syn* and *anti* conformations of the CNNN moiety, the *anti* being the more stable form. The electron diffraction analysis yielded the following bond lengths ( $r_g$ ), bond angles, and torsional angles: C—H 1.111(5) Å, (N—N)<sub>terminal</sub> 1.143(4) Å, (N—N)<sub>central</sub> 1.240(5) Å, (C—C)<sub>mean</sub> 1.534(3) Å,  $\angle$ N—N—N 171.8°,  $\angle$ N—N—C 118.6°,  $\angle$ N—C—C 102.5° and 110.5°,  $\angle$ C—C—H 111.2°,  $\angle$ C—C—C 110.2° and 112.6°,  $\angle$ N—N—C—C 167.5°, 50.1° and -75.2°.

When calculating rotational barriers for methyl azide, and ethyl azide with *ab initio* methods, the results are very sensitive to the basis set quality and to the consideration of electron correlation [152]. For methyl azide a very good agreement between theory (2.9 kJ/mol) and experiment (2.98 kJ/mol) was observed for calculations. For ethyl azide, results suggested that a correct theoretical evaluation of the rotational barrier between the *anti* and *gauche* conformers cannot be carried out at the Hartree-Fock level for which the barriers were in the 0.8–1.4 kJ/mol range.

The geometries of the molecular structures of 55 organic azides were fully optimized by using semi-empirical molecular orbital (MO) methods of Austin Model 1 (AM1), Møller-Plesset (perturbation theory) (PM3), modified neglect of diatomic overlap (MNDO), and modified intermediate neglect of differential overlap (MINDO/3) [153]. Compared with the available experimental geometry parameters in gaseous phase, it was found that the calculation error from AM1 was the smallest and the next best ones are those from PM3 and MNDO. Among four MO methods used, the heat of formation computed with AM1 was the closest to the results obtained from the group additivity method. The results from MINDO/3 were the worst.

Geometries and electronic structures of methyl azide vapor and its dimers have been calculated by using *ab initio* methods at the Hartree-Fock (HF) level [154]. The intermolecular interaction energy was calculated with MP2 electron correlation correction, basis set superposition error (BSSE) correction and zero point energy (ZPE) correction. The most stable dimer with a binding energy of 9.49 kJ/mol has a six-membered ring structure with two C—H...N hydrogen bonds and belongs to the  $D_{2h}$  space group. The effect of methyl internal rotation on the interaction energy was investigated. A natural bond orbital analysis was performed to reveal the origin of the interaction.

The molecular structures of 30 azido compounds were optimized with the Becke, 3-parameter, Lee-Yang-Parr (B3LYP) method of density functional theory using six basis sets and semi-empirical PM3 and AM1 methods [155]. The molar volumes based on the isoelectron density contour were evaluated using a Monte Carlo integration scheme and the integral equation formalism polarized continuum model. The densi-

ties were subsequently predicted. Excellent linear correlations were found between the results obtained with the two models, and different methods had little effect on the densities. Quantitative relationships were established with the calculated and experimental densities of 25 azido compounds, and were used to predict the densities of five other azido compounds in the testing set. The predicted densities agreed well with the experimental data.

### 3.3 Chemical Properties of Organic Azides

The reactivity of organic azides is desirable on the one hand because it increases burning rates and specific impulse, but on the other hand it also increases sensitivity which may increase processing cost, or the propellant ends up in a higher hazard class (not low vulnerability ammunition – LOVA).

#### 3.3.1 Reactions of Organic Azides

Organic azides are quite reactive and can be used for the synthesis of many other organic compounds. The Curtius rearrangement is based on the intermediate formation of an acyl azide in the reaction. The Curtius rearrangement is the thermal decomposition of an acyl azide to an isocyanate with the loss of dinitrogen gas. The isocyanate can then undergo attack by a variety of nucleophiles such as water, alcohols or amines, to yield a primary amine, carbamate or a urea derivative, respectively:

Acyl azides can be obtained by treating acylhydrazines with nitrous acid. Some azido compounds are 1,3-dipoles, which are used in cycloadditions forming heterocyclic compounds.

The Schmidt reaction is an organic reaction involving alkyl migration over the carbon-nitrogen chemical bond in an azide with expulsion of nitrogen under the influence of a catalyst that can be a protic acid, usually sulfuric acid or a Lewis acid. The key reagent introducing this azide group is hydrazoic acid and the reaction product depends on the type of reactant: In this reaction, carboxylic acids form amines through an isocyanate intermediate and ketones form amides.

Trihalogenoamines, such as nitrogen trichloride or nitrogen triiodide are notoriously unstable and detonate even at the slightest stimulus. One would not expect triazidoamine  $N(N_3)_3$  to be any more stable, if it even exists. Calculations have shown it to contain much energy and it would leave pollution-free exhaust if it could be used in gas generants or rocket engines [156]. Maybe the molecule would be more stable if ethylene groups would be inserted between the central nitrogen atom and the three azido groups. The energy level of tris(2-azidoethyl)amine was also calculated and indicated that it should be stable. This compound was described in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines.”

### 3.3.2 Decomposition of Organic Azides

This section contains only kinetic and thermochemical studies of the decomposition of organic azides. Combustion in flame reactions, with or without additional oxidizer, will be discussed in *Encyclopedia of Monopropellants*, chapter “Organic Monopropellants.” Strand burning of azido compounds in the absence of air is described in section “Strand Burning of Organic Azides” and section “Strand Burning of 2-Azidoethanol.”

Simple alkyl azides, such as methyl azide, have been studied as model compounds in order to better understand the decomposition of more complex azido compounds which have more practical value than methyl azide. The decomposition of methyl azide is only of academic interest. The same is the case for decomposition studies of hydrogen azide, which of course nobody wants to use as a rocket propellant. The study of the decomposition of methyl azide and the other lower alkyl azides is being done for similar reasons like the study of methylnitramine. Like methyl azide, methylnitramine is not used as rocket propellant, but because it is a simple molecule it is easier to study its decomposition mechanism. It thus serves as a model compound for the decomposition of more complex organic azides.

An excellent summary of decomposition reactions of organic azides initiated by various stimuli like acid, heat, light or transition metal catalysts is available for further study of this topic [109].

The thermal decompositions of azido compounds can proceed by two different pathways, by way of ionic and covalent bonds. Most organic azido compounds are covalent azido compounds. The electromagnetivity of the  $-N_3$  group strengthens the C—N bond. So, the bond lengths of two N—N bonds in  $-N_3$  groups are different. The bond lengths of pairs of nitrogens in the azido groups are

The decomposition of azido compounds proceeds by the following equation:

The nitrene with a free electron pair is unstable and undergoes further decomposition.

The simplest alkyl azide and easiest to investigate for its decomposition kinetics is methyl azide. The thermal decomposition of methyl azide or ethyl azide is a homogeneous unimolecular reaction [157].

Alkyl azides tend to explode violently when ignited in the condensed phase but can be heated in low-pressure gas flow pyrolysis systems without much risk [158].

*Ab initio* MO calculations have been used to study the decomposition of methyl azide, methanimine  $\text{H}_2\text{C}=\text{NH}$ , and its isomers ( $\text{CH}_3\text{N}$ ) in order to explain the formation of HCN as a decomposition product [159]. The heat of formation of methyl azide vapor was estimated as  $305.8 \pm 12.5 \text{ kJ/mol}$  ( $73.1 \pm 3 \text{ kcal/mol}$ ). It appears that HCN is not directly formed upon fragmentation of methanimine but rather from rearrangement of HNC which is the primary product. The HCN formation from either methylnitrene or methanimine passes through successive losses of H atoms.

The thermal decomposition of methyl azide has been studied computationally and the reaction was predicted to occur in two steps via nitrene intermediate [160, 161]. The rate-limiting step is the  $\text{N}_2$  extrusion:

The potential energy surfaces of ethyl azide relevant to its thermal decomposition have been studied theoretically [162]. The reaction mechanism can be described by the following steps, like the methyl azide decomposition steps shown above:

The  $\text{CN}-\text{N}_2$  fission of ethyl azide is the rate limiting step (1), leading to ethylnitrene either along a spin-allowed path (2a) or along an alternative spin-forbidden one (2b). Both 1a and 1b channels show barriers of similar heights for  $\text{CN}-\text{N}_2$  bond fission,  $\Delta E = 42 \text{ kcal/mol}$ ,  $\Delta E$  being the energy difference between the minimum of the ground singlet state potential energy surface of ethyl azide and either the singlet transition state (TS1) or the lowest energy point of the intersystem crossing (ISC1), respectively. The decomposition of ethanimine formed in step (2b) has been studied as well and high energetic transition states have been identified for its decomposition.

Dinitrogen  $\text{N}_2$  extrusion from hydrazoic acid, methyl azide, and ethyl azide to yield the corresponding nitrene has been studied with high-level *ab initio* calculations [163]. The decomposition reaction is a competitive mechanism between a spin-allowed and a spin-forbidden channel, giving the nitrene either in the singlet or triplet states. The energy barrier height for  $\text{XN}-\text{N}_2$  bond fission is approximately the same in both channels for each azide.

The thermal decomposition of methyl azidoformate ( $\text{N}_3\text{COOMe}$ ), ethyl azidoformate ( $\text{N}_3\text{COOEt}$ ) and 2-azido-*N,N*-dimethylacetamide ( $\text{N}_3\text{CH}_2\text{CONMe}_2$ ) have been studied by matrix isolation IR spectroscopy and real-time UV photoelectron spectroscopy [164]. Dinitrogen  $\text{N}_2$  appeared as an initial pyrolysis product in all systems, and the next question is about the fate of the accompanying organic fragment. For methyl azidoformate, four accompanying products were observed:  $\text{HNCO}$ ,  $\text{H}_2\text{CO}$ ,  $\text{CH}_2\text{NH}$ , and  $\text{CO}_2$ , and these are believed to arise as a result of two competing decomposition routes of a four-membered cyclic intermediate. Ethyl azidoformate pyrolysis gave four corresponding products:  $\text{HNCO}$ ,  $\text{MeCHO}$ ,  $\text{MeCHNH}$ , and  $\text{CO}_2$ , together with the five-membered-ring compound 2-oxazolidone. Mechanisms were proposed for the formation and decomposition of all the products observed in these three systems, based on the experimental evidence and the results of supporting molecular orbital calculations.

The thermal decomposition of ethyl azide, *n*-propyl azide, and isopropyl azide was investigated by two different methods, a static method and a dynamic method [165]. Above a pressure of 25 mm Hg the kinetic rate was independent of pressure and typical for a homogeneous first order reaction. The kinetic rates can be expressed by the equations listed in Table 8.

**Table 8:** Kinetic rate equations for decomposition of alkyl azides.

| Compound               | Rate equation                                                  |
|------------------------|----------------------------------------------------------------|
| Ethyl azide            | $k_\infty = 3.30 \times 10^{14} \exp(40100/RT) \text{ s}^{-1}$ |
| <i>n</i> -Propyl azide | $k_\infty = 1.50 \times 10^{14} \exp(39400/RT) \text{ s}^{-1}$ |
| Isopropyl azide        | $k_\infty = 7.20 \times 10^{13} \exp(38500/RT) \text{ s}^{-1}$ |

Data source: [165]

Flash vacuum pyrolysis of azides is a very valuable method of generating nitrenes and studying their thermal rearrangements. The nitrenes can in many cases be isolated in low-temperature matrices and observed spectroscopically.  $\text{NH}$  and methyl, alkyl, aralkyl, vinyl, cyano, aryl and *N*-heteroaryl, acyl, carbamoyl, alkoxycarbonyl, imido, boryl, silyl, phosphonyl, and sulfonyl nitrenes can be made in this way [166]. Flash pyrolysis can be achieved under flow conditions or in solution or the solid state, and by photolysis.

### 3.4 Strand Burning of Organic Azides

Liquid organic azides have been evaluated as energetic plasticizers for solid propellants and as monopropellants. Linear strand burning rates have been measured as a quantitative measure of their reactivity and in preparation for their use as monopro-

pellants. Individual chapters in this book will discuss strand burning rates of GAP and 2-azidoethanol and their evaluation as monopropellants. Burning rates and critical diameters for flame propagation of several other alkyl azides have been investigated [167]. This study included 1,5-diazidopentane, 1,3-diazidopropan-2-ol, and two of its esters (Table 9).

**Table 9:** Properties of azido compounds.

| Compound name                                       | Formula                                                                                                        | Molec-<br>ular<br>mass | Density<br>at 293 K | Boiling<br>point at<br>reduced<br>pressure | Vis-<br>cosity<br>at<br>293 K | Nitro-<br>gen<br>content |

Data source: [167]

The azido derivatives were obtained and refined by methods described in the literature. The critical combustion diameters for the azido compounds under investigation were determined by a strand burning method. To diminish the possibility of heat transfer along the walls of the glass cones and tubes, these latter were placed in a vessel with a cooling fluid (water, glycerin). The following features were noted during determination of the critical combustion diameters: A flame was detected for DAG (fine, 2mm, blue-tinted luminous zone located on the fluid surface), for DAPEN (pale-blue-tinted flame and more extensive in height than for DAG), and also for DAPA (very pale, noticeable only in the dark). A flame was completely absent for DAPP.

### 3.5 Handling Precautions for Working with Organic Azides

An excellent summary of safe handling procedures for working with organic azides is given in [168]. It contains a detailed description of the sensitivity testing instruments used to characterize handling hazards of organic azides and compares it to the sensitivity of well-characterized explosives like glycerol trinitrate or TNT.

**Table 10:** Physical properties and impact sensitivity of nitroalkyl and heterocyclic azides.

| No. | Compound                                                                                                                                            | H50<br>cm | T<br>K | T<br>°C | $\Delta H_f^\circ$<br>kJ/mol | $\Delta H_f^\circ$<br>kcal/mol | $\rho$<br>g/cm <sup>3</sup> | $Q_{\max}$<br>kcal/g | $\rho Q_{\max}$<br>kcal/cm <sup>3</sup> |
|-----|-----------------------------------------------------------------------------------------------------------------------------------------------------|-----------|--------|---------|------------------------------|--------------------------------|-----------------------------|----------------------|-----------------------------------------|
| 35  | (N <sub>3</sub> CH <sub>2</sub> ) <sub>2</sub> NNO <sub>2</sub>                                                                                     | 1.8       | 293    | 20      | 664                          | 158.6                          | 1.45                        | 1.716                | 2.49                                    |

Data source: [169]

### 3.6 Impact Sensitivity of Alkyl Azides

Drop weight impact sensitivities of 58 liquid explosives and melts of high explosives were summarized in [169]. Compounds that were solids at room temperature were heated to just above their melting points. That publication contained data for eight azidonitro compounds. The data for individual alkyl azides were extracted from that table and shown here (Table 10). The compound numbers in the first column of the table are the same as those used in Figure 6 below. As shown in Figure 6, a linear correlation between impact sensitivity and their maximum volumetric heats of explosion could be established, like the one already shown for nitroalkanes and alkyl nitrates.

**Figure 6:** Correlation between the sensitivity of nitroalkyl azides and their maximum volumetric heats of explosion (republished and modified from [169], with permission of ©2010 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

### 3.7 Applications of Organic Azides

There are many applications of organic azides in addition to their uses in energetic binders, plasticizers, bipropellant fuels, and monopropellants. All these applications have been investigated in many other parts of the world [128, 170].

#### 3.7.1 Applications as Binders and Plasticizers

Many organic azides serve as energetic binders and plasticizers in various solid propellants. Most of the applications of azides are in solid propellants and only very few

(if any) are in liquid propellant fuels or monopropellants. For example, low-molecular-weight GAP oligomers have been used as energetic plasticizers.

### 3.7.2 Azide Additives to Fuels Enhance Droplet Dispersion by Microexplosions

Alkyl and aryl azides have been evaluated as additives to diesel engine fuels, jet engine fuels, and rocket fuels. The sudden decomposition of azides dissolved in jet engine fuel when heated in the flame zone would cause the hydrocarbon fuel droplets to break up under the influence of microexplosions sooner, scatter smaller droplets around, and burn faster in air in the combustor of jet engines, allowing more compact designs of combustion chambers. The rate of vaporization of fuel droplets can be increased by up to two orders of magnitude by addition of azides [139, 171–173]. The combustion characteristics of droplets of four energetic fuels, namely, 1) 1,4-dimethyl ester cubane (which is a solid and slightly soluble in conventional liquid fuels), 2) dihydrobenzvalene, 3) phenyl azide, and 4) carborane (which are all liquids), were examined experimentally [174]. The three liquid fuels all soot profusely, with the sooting propensity, when compared with other fuels, being in the following order: JP-10 < dihydrobenzvalene < phenyl azide < carborane; and that phenyl azide exhibits fast gasification rates and advanced microexplosion events. It was emphasized that a high energy density fuel does not automatically imply that it is fast burning, and that it must also possess desirable combustion characteristics, especially minimal sooting formation, before it can be considered for use as a jet fuel or jet fuel additive.

## 4 Organic Azides with One Azido Group

Organic azides are useful reactants in 1,3 dipolar cycloadditions to acetylenes (alkynes), which lead to five-membered heterocycles.

### 4.1 Methyl Azide

Methyl azide, azidomethane,  $\text{H}_3\text{CN}_3$ ,  $\text{CH}_3\text{N}_3$ , CAS RN [624-90-8],  $M = 57.0546 \text{ g/mol} = 17.527 \text{ mol/kg}$ , the lowest member of the family of alkyl azides, is often used as a model substance in kinetic studies on the thermal and photolytic decomposition of organic azides. Some of the properties of methyl azide were already listed in Table 5.

The molecular structure of methyl azide has been derived from Raman spectra and electron diffraction experiments and discussed in terms of the adjacent charge rule in comparison to methyl nitrate [175].

## 4.2 Ethyl Azide

Ethyl azide, azidoethane, 1-azidoethane,  $\text{H}_3\text{CCH}_2\text{N}_3$ ,  $\text{C}_2\text{H}_5\text{N}_3$ , CAS RN [871-31-8],  $M = 71.0812 \text{ g/mol} = 14.068 \text{ mol/kg}$ , is often used as a model substance in kinetic studies on the thermal and photolytic decomposition of organic azides. Some of the properties of ethyl azide were already listed in Tables 5 and 7. Ethyl azide is a liquid with a boiling point of 321.9–323.0 K at 102 kPa (48.8–50 °C at 766 mm Hg) and a density of  $0.8765 \text{ g/cm}^3$  at 298 K, and a refractive index  $n_D^{25}$  of 1.3928.

The standard enthalpy of formation of ethyl azide liquid is +266.872 kJ/mol. Ethyl azide is the parent compound of 2-dimethylaminoethyl azide (DMAZ), a thoroughly investigated compound intended as a less toxic hypergolic fuel replacement for MMH. The molecular structure of ethyl azide was illustrated in Figure 5. Ethyl azide detonates when stimulated with enough energy [176, 177].

## 4.3 2-Azidoethanol

2-Azidoethanol, also known as  $\beta$ -azidoethanol, 1-azido-2-hydroxyethane; ethanol, 2-triazo-;  $\text{N}_3\text{CH}_2\text{CH}_2\text{OH}$ ,  $\text{C}_2\text{H}_5\text{N}_3\text{O}$ , AZET, CAS RN [1517-05-1],  $M = 87.08 \text{ g/mol} = 11.48 \text{ mol/kg}$ , is discussed here under azido compounds, because its properties are dominated by the presence of the azido group and the presence of the hydroxyl group is only peripheral. The decision about its location in this chapter is counter to the decision to discuss DMAZ under amines instead of azides. DMAZ was assigned a section in the chapter on amines because the amine is the core of the molecule and the azido group is only an appendage. At one time we considered to move AZET to the alcohols in *Encyclopedia of Liquid Fuels*, chapter “Alcohols.” The current azide chapter was at one time reserved for alkyl azido compounds that did not carry other substituents in the alkyl group.

2-Azidoethanol can be made by azidation from ethylene chlorohydrin in water followed by distillation under vacuum. There has been an accidental explosion during the preparation of 2-azidoethanol [178]. 2-Azidoethanol can be made from a mixture of 2-chloroethanol (0.080 g) and sodium azide (0.072 g) with microwave irradiation [179]. The melting point given for 2-azidoethanol in [179], m.p. = 463 K (190 °C) is **incorrect**. Some literature describes the preparation of 2-azidoethanol without any warnings about its explosive properties [180].

### 4.3.1 Physical Properties of 2-Azidoethanol

2-Azidoethanol is a liquid with a boiling point of 333 K at 1.07 kPa and 346 K at 2.7 kPa (60 °C at 8 mm Hg and 73 °C at 20 mm Hg), a density of  $1.1435 \text{ g/cm}^3$  at 298 K and a refractive index of  $n_D^{20} = 1.4610$ . The oxygen balance of 2-azidoethanol for combustion to  $\text{CO}_2$  is –101%. The heat of evaporation of 2-azidoethanol at 298 K is

$62.21 \pm 0.28$  kJ/mol. The vapor pressure of 2-azidoethanol can be calculated from the equation [140]:

$$\ln P = 308.60/R - 81497.03/RT - \frac{64.7}{R} \ln(T/298.15)$$

where  $P$  is the vapor pressure in Pa and  $T$  is the temperature in kelvin, and  $R$  is the gas constant  $R = 8.3143 \text{ J K}^{-1} \text{ mol}^{-1}$ . This equation translates into a normal boiling point at atmospheric pressure of 432 K (159 °C), but that is not a safe temperature to heat AZET to. AZET can be safely distilled under a vacuum of 30 Pa where it boils at 344 K (71 °C). The refractive index of AZET is  $n_D^{20} = 1.4610$ .

The enthalpy of formation of liquid azidoethanol is +94.14 kJ/mol (+22.5 kcal/mol), which is substantially higher than the enthalpy of formation of ethanol, which is -278 kJ/mol (-66.3 kcal/mol). Substituting one hydrogen in the beta position with azide thus makes a difference of 88.8 kcal/mol thanks to the addition of azide.

The predicted computed gas phase enthalpy of formation of 2-azidoethanol,  $\text{HOCH}_2\text{CH}_2\text{N}_3$ , ranged from +112.5 to +117.6 kJ/mol with an average of +114.7 kJ/mol [147].

The PEPCODED.DAT data file has a similar enthalpy of formation of +258 cal/g = +22.47 kcal/mol = +94.0 kJ/mol for liquid AZET [7]. The density is listed there as  $0.0415 \text{ lb/in.}^3 = 1.149 \text{ g/cm}^3$ .

The addition of each azido groups to a molecule contributes a positive increase in the enthalpy of formation of 313–397 kJ/mol. This is evident from a comparison of enthalpy of formation of ethanol (-278.5 kJ/mol) and 2-azidoethanol,  $\text{N}_3\text{CH}_2\text{CH}_2\text{OH}$  (+104 kJ/mol).

A homologue of 2-azidoethanol is 3-azidopropanol, CAS RN [72320-38-8], refractive index  $n_D^{20} = 1.461$ , density  $\rho = 1.095 \text{ g/cm}^3$  at 298 K (25 °C), which is commercially available. Its isomer 3-azido-1-methyl-ethanol is also commercially available.

#### 4.3.1.1 Molecular Structure of 2-Azidoethanol

The molecular structure of 2-azidoethanol is illustrated in Figure 7.

**Figure 7:** Molecular structure of 2-azidoethanol.

### 4.3.2 Chemical Properties of 2-Azidoethanol

The hydroxyl group in 2-azidoethanol can be esterized with nitric acid, giving 2-azido-1-ethanol nitrate,  $\text{N}_3\text{CH}_2\text{CH}_2\text{ONO}_2$ , ethanol azido nitrate, which is a volatile liquid with a density of  $1.34 \text{ g/cm}^3$  and a freezing point of  $253 \text{ K}$  ( $-20^\circ\text{C}$ ).

#### 4.3.2.1 Reactions of 2-Azidoethanol

2-Azidoethanol ignites hypergolically with high concentration hydrogen peroxide [181, 182].

#### 4.3.2.2 Thermal Decomposition of 2-Azidoethanol

2-Azidoethanol has been considered as a monopropellant, thus its decomposition in reactors at high pressures will be discussed in *Encyclopedia of Monopropellants*. Here we are only looking at some academic studies of its decomposition mechanism, studies that can be carried out in glass apparatus at low pressure. A section on strand burning of 2-azidoethanol follows the current section in this chapter.

The thermal decomposition of 2-azidoethanol and 2-azidoethyl acetate was studied by matrix isolation IR spectroscopy and real-time UV photoelectron spectroscopy [183]. The products that were detected in a flow system at different temperatures ( $\text{CH}_2\text{NH}$ ,  $\text{H}_2\text{CO}$ ,  $\text{N}_2$ ,  $\text{CO}$ , and  $\text{HCN}$ ) allowed mechanisms for decomposition to be proposed. The experimental evidence obtained is consistent with 2-azidoethanol decomposing via a stepwise decomposition mechanism as observed previously for azidoacetone.

The temperature dependence of the saturated vapor pressure of 2-azidoethanol was determined and the evaporation enthalpy, evaporation entropy and boiling point of this substance were  $33.9 \pm 1.2 \text{ kJ/mol}$  ( $8.1 \pm 0.3 \text{ kcal/mol}$ ),  $17.7 \pm 0.5 \text{ e.u.}$  and  $458 \text{ K}$  ( $185^\circ\text{C}$ ), respectively [184]. These numbers showed that 2-azidoethanol is a weakly associated liquid. Kinetics of the thermal decomposition of 2-azidoethanol in the gas phase can be described by an equation of the first order. Nitrogen and ethanolamine were found among the products of decomposition. The rate constant of the process did not depend on the initial gas pressure. The reaction has a partially heterogeneous character; however, the contribution of heterogeneous reaction to observable kinetics was negligible. It is assumed that the reaction proceeds with neighboring group participation (anchimeric assistance) by the hydroxyl group. The kinetic data were used for prediction of parameters of adiabatic explosion and combustion of 2-azidoethanol at higher pressure.

In a study of the pyrolysis of 2-azidoethanol it was found that a Curtius type rearrangement plays an important role in the pyrolysis reaction [185]. Two imine intermediates have been found in the pyrolysis reaction and the most likely pyrolysis products were  $\text{HCHO}$ ,  $\text{CH}_2=\text{NH}$ ,  $\text{HCN}$ , and  $\text{N}_2$ .

### 4.3.3 Strand Burning of 2-Azidoethanol

The strand burning and droplet burning of azidoethanol is of interest for its potential application as a monopropellant.

The strand burning rate and the critical diameter for propagation of combustion of 2-azidoethanol in capillary glass tubes were determined in a constant pressure bomb as a function of pressure [186]. The critical diameter when plotted against pressure showed two distinctly different regimes, a laminar steady combustion and a turbulent combustion. The critical diameter was below 1 mm when the pressure was increased beyond  $10^5$  Pa. This is a very small critical diameter, smaller than those observed with other monopropellants. The strand burning rate of 2-azidoethanol as a function of pressure is illustrated in Figure 8. The curves are for different capillary diameters. The diameters are identified in the legend to the figure. The smallest diameters are those shown with solid triangles (0.72 mm) and open squares symbols (0.94 mm).

**Figure 8:** Strand burning rate of 2-azidoethanol as a function of pressure (republished and modified from [186], with permission of ©1981 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

During the burning of 2-azidoethanol, pyrolysis with a rate constant

$$k = 0.794 \times 10^4 \exp(-37800/RT) \text{s}^{-1}$$

is the predominant reaction, where the combustion and the limiting conditions are closely described by the Zeldovich and Frank-Kamenetskii thermal theory [187, 188]. Measurements of the burning of 2-azidoethanol droplets in air were made by placing the droplets on a thin nichrome support and igniting them with a tungsten filament through which a current was passed. The external pressure effect on the burning rate was examined in a vacuum chamber fitted with two viewing windows. The surface area  $S$  decreased linearly with time at all pressures, so the rate can be characterized by the constant  $K = dS/dt$ ; however, at atmospheric pressure,  $K$  varied linearly with  $r^2$ . Above 0.2 kPa, there was a secondary flame, and the combustion rate increased to  $0.4 \text{ g cm}^{-2} \text{ s}^{-1}$  at atmospheric pressure.

During 2-azidoethanol combustion at lowered pressures in air in non-thermostatted tubes the heat supply along the tube walls from the decomposition zone to the condensed phase may lead to a transition of azidoethanol combustion to a pulsating regime [189].

A distinctive feature of the dependence of the combustion velocity of azidoethanol on the external pressure was that a density jump developed during the transition from normal combustion to a fluctuating regime. The periods of the fluctuations in the combustion velocity of azidoethanol were determined for different external pressures [190].

It was found that there are three regimes of ignition of individual drops that differ in kinetics of chemical reactions [191]. The first regime showed a temperature interval where oxidation and decomposition occurred simultaneously at ignition process of 2-azidoethanol. The burning rates of liquid 2-azidoethanol gelled with polymethyl methacrylate (PMMA) and placed into thin tubes with diameters of  $d = 2 - 10 \text{ mm}$  also had a pulsed character [192]. The burning rate of gelled 2-azidoethanol increased with pressures from 13 to 260 GPa in accordance with the linear law. The combustion of gelled 2-azidoethanol transitioned to turbulent regime at pressures above 260 GPa. Such transition was accompanied by an increase of burning rate by a factor of 5–6.

The flame of 2-azidoethanol burning in thin capillary tubes at atmospheric pressure has two combustion zones [193]. The first combustion front is near the surface where the reaction is a decomposition reaction of the azide group. The second combustion zone is above the upper edge of the capillary tube and has the form of a steady flame torch (secondary flame). The reaction in the secondary flame is an oxidizing reaction of decomposition reaction products with oxygen from ambient air.

The ignition delay of 2-azidoethanol in air dropped steeply from 17 s at 500 K to 1 s at 625 K and remained below 2 s between 625 and 725 K. When studying the behavior of a droplet of 2-azidoethanol in heated air, it was shown that droplet ignition

is a gas-phase process limited by heat release due to the vapor-phase oxidation of azidoethanol [194]. An increase in the ambient temperature with distance from the ignition limit leads to enhancement of the role of the thermal decomposition of azidoethanol molecules. In the range of ambient temperatures of 560–620 K, the droplet ignition is determined by the kinetics of the parallel reactions, the gas-phase oxidation and thermal decomposition of azidoethanol. The activation energy of the chemical reaction limiting the droplet ignition process was estimated to be  $E_a = 60.7 \pm 2.9$  kJ/mol ( $14.5 \pm 0.7$  kcal/mol). The value obtained is much lower than the activation energy for the thermal decomposition reaction of  $\beta$ -azidoethanol molecules, for which the reaction rate constant is  $k_2 = 8 \times 10^{13} \exp(-37800/RT) \text{ s}^{-1}$ . Thermocouples were used to study the oscillatory combustion of 2-azidoethanol [195].

#### 4.3.4 Safety Properties of 2-Azidoethanol

In view of accidental explosions that have occurred during the preparation of 2-azidoethanol, it is important to know the safety properties of this material [178]. An explosion with a force equivalent to 100–200 g TNT occurred during the preparation of 2-azidoethanol, CAS RN [1517-05-1] 1 h and 40 min. after 1.831 kg 2-bromoethanol had been added to 1.03 kg sodium azide. The homogeneous mixture was being maintained at steam bath temperature under stirring.

Limits of initiation of explosion of homogeneous liquid explosives can be determined by recording luminosity of shock waves during intersection at the contact interface of a non-explosive and an explosive liquid. The method was demonstrated by determining the limits of initiation of the detonation of azidoethanol [196].

Sensitivity tests of gelled non-Newtonian liquid propellants containing AZET, 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), triaminoguanidinium nitrate (TAGN), and a gelling agent showed that these propellants were less sensitive than the pure ingredients from which they were made [197, 198].

#### 4.4 2-Azido-*N,N*-dimethylethanamine

2-Azido-*N,N*-dimethylethylamine, also known as *N,N*-dimethyl-2-azidoethylamine, 2-azidoethyl-*N,N*-dimethylamine, 2-azido-*N,N*-dimethylethanamine,  $(\text{CH}_3)_2\text{NCH}_2\text{CH}_2\text{N}_3$ ,  $\text{C}_4\text{H}_{10}\text{N}_4$ , DMAZ, CAS RN [86147-04-8] is a candidate fuel to replace hydrazine derivatives, especially MMH, in certain hypergolic fuel bipropellant applications. It can also decompose by itself in a monopropellant fashion and has been considered as a replacement for hydrazine as a monopropellant. Properties of DMAZ will be discussed in *Encyclopedia of Liquid Fuels*, chapter “Aliphatic Amines,” because the core of the molecule is an amine and the azide is only an attachment.

## 4.5 Propyl Azides

1-Azidopropane, *n*-propyl azide,  $C_3H_7N_3$ , can be made from a mixture of 1-bromopropane (0.122 g) and sodium azide (0.072 g) with microwave irradiation for 29 min. [179]. The melting point given in [179] (206 °C) is **incorrect**. A similar method starting with a mixture of 2-bromopropane (0.122 g) and sodium azide (0.072 g) gives 2-azidopropane. 3-Azidopropane-1,2-diol has been used as a chain extender for GAP solid propellant polyurethane binders.

## 4.6 Glycidyl Azide

Glycidyl azide,  $CH_2(O)CHCH_2N_3$ , GAP, CAS RN [80044-09-3], has been extensively investigated as the monomer that can be polymerized to form an energetic binder for solid propellant. Instead of allowing the polymerization to go to high molecular masses resulting in solid, flexible polymers, the polymerization can be interrupted after only a small number of monomer molecules have been linked to form liquid oligomers. Oligomers (telomers) of GAP can be used as energetic plasticizers. Oligomers can be formed with different end groups in the telomer. GAP has a low glass transition temperature (228 K = −45 °C). The functionality of linear GAP is nearly 2, and to achieve the desired level of crosslinking to produce a tough and elastomeric rubber it must be raised by the addition of triols or used with triisocyanate crosslinkers. Some of the methods described here in the chapter on plasticizers can also be applied to the synthesis of GAP products with higher molecular masses. Properties of GAP diol and GAP triol are summarized in Table 11. The precursor epichlorohydrin diol is commercially available. The synthesis of GAP triol starts with epichlorohydrin and glycerol.

**Table 11:** Properties of GAP diol and GAP triol.

|                                                          | GAP diol            | GAP triol           |

Data source: [199]

A convenient process for the preparation of low molecular weight hydroxyl-terminated glycidyl azide polymers involved the formation of glycidyl azide polymer in a single step [200]. The polymerization of epichlorohydrin was carried out in dipolar aprotic solvent *N,N*-dimethylformamide medium using diols as initiators in the presence of sodium azide. Various low molecular weight diols, such as ethylene glycol, propylene glycol, diethylene glycol, 2-methylpentane-2,4-diol and resorcinol were employed as initiators. The effect of different initiating diols on the polymer formation was confirmed by gel permeation chromatography (GPC) and vapor pressure osmometry (VPO). The GPC analysis indicated that the glycidyl azide polymers contained different-sized oligomers due to the multi-modal molecular weight distribution. The GAPs obtained in all the polymerizations by using different diols had a maximum of 5–7 glycidyl azide repeating units. The low-molecular weight GAPs obtained by using different diol units had a thermal decomposition pattern like that of GAP. Since the glycidyl azide polymers had low molecular weights, their glass transition temperatures were lower, between 203 and 201 K (between  $-70$  and  $-72^{\circ}\text{C}$ ).

In addition to poly(glycidyl azide) oligomers terminating in hydroxyl groups, oligomers with terminal azido groups (GAPA) have been synthesized. As a general rule, plasticizing effects will be lost if terminal hydroxyl groups on the plasticizer react with the isocyanate crosslinking agent, effectively tying the plasticizer into the cross-linked polymer matrix. An azide-terminated glycidyl azide plasticizer (GAPA) avoids this problem, being a plasticizer having no reactive terminal hydroxyl groups available for isocyanate reactions [201]. GAPA is produced by reacting polyepichlorohydrin with *p*-toluenesulfonyl chloride in pyridine and reacting the resulting tosylated polyepichlorohydrin with sodium azide in dimethylformamide. GAPA is a pale-yellow liquid with low molecular weight, low  $T_g$ , and good thermal stability (Table 12).

Low-molecular-weight GAP oligomers have been used as energetic plasticizers, in particular for propellants with ingredients that are not compatible with nitrate-ester energetic plasticizers. One of these propellants used TAGN with a GAP plasticizer [202].

The thermal stability of a special type of GAP plasticizer at one time available from 3M as L-12616 was studied at elevated temperatures [203]. Little change was observed

**Table 12:** Properties of azide terminated glycidyl azide plasticizer (GAPA).

|                                                          |                     |
|----------------------------------------------------------|---------------------|
| $\Delta H_f$ , J/g                                       | 2301                |
| $\Delta H_f$ , cal/g                                     | 550                 |

Data source: [199]

at temperatures up to 383 K (110 °C) but aging at 423 K (150 °C) resulted in the formation of volatile, lower molecular weight species. Aging effects were less pronounced in air than in an inert atmosphere.

Low molecular mass hydroxyl-terminated glycidyl azide polymers can be made in a single step by polymerization of epichlorohydrin in dipolar aprotic solvent *N,N*-dimethylformamide (DMF) using diols as initiators in the presence of sodium azide [200]. Various low molecular mass diols, such as ethylene glycol, propylene glycol, diethylene glycol, 2-methylpentane-2,4-diol, and resorcinol were employed as initiators. The effect of initiating diols on the polymer formation was confirmed by GPC and VPO. The GPC analysis indicated that the glycidyl azide polymers contained different size oligomers, due to the multi-modal molecular weight distribution. Since the glycidyl azide polymers have low molecular mass, their glass transition temperatures are lower, between 203 and 201 K (–70 and –72 °C), due to variations in the structure of the polymers. Structural analysis of the GAPs using spectral methods revealed that the initiating diol units were present in the polyether backbone of GAP molecules.

Polyepichlorohydrin (PECH) precursor was synthesized by the ring-opening polymerization of epichlorohydrin using 1,4-butanediol as initiator and boron-trifluoride etherate as catalyst [204]. The second step of tosylation made tosylate-terminated epichlorohydrin polymer as intermediate by reaction of PECH and 4-toluenesulfonylchloride in pyridine. The third step yielded azido terminated glycidyl azide polymer (ATGAP) by the reaction of tosylate intermediate and sodium azide. The structure of ATGAP was characterized by IR, <sup>1</sup>H NMR, and <sup>13</sup>C NMR. The glass transition temperature of ATGAP was 200 K (–73 °C). The onset of thermal decomposition temperature was 526 K (253 °C). ATGAP has a low viscosity and can be used as an energetic plasticizer.

There are two routes to the preparation of oligo (glycidyl azides): first, oligomerization of glycidyl azide and second, oligomerization of its halogen-containing precursors (oligoepichlorohydrin or oligoepibromohydrin) with simultaneous or subsequent substitution of azide groups for the halogen atoms. The first route is difficult to follow on account of the low reactivity of glycidyl azide. Instead

oligo(glycidyl azides) were prepared by the second route [205]. Prepolymers of different modifications were obtained by cationic polymerization of epichlorohydrin under the action of  $\text{BF}_3 \cdot \text{THF}$ . The synthesis of azide-substituted polymers, such as glycidyl azide and 3,3'-bis(azidomethyl)oxetane (azidopentone) polymers can be made by the azidation of their halogen-containing precursors with sodium azide in a dimethyl sulfoxide (DMSO) ( $353 \text{ K} = 80^\circ\text{C}$ , 10–100 h) or DMF medium ( $368 \text{ K} = 95^\circ\text{C}$ , 10–20 h). The synthesis of poly(glycidyl azides) by the simultaneous polymerization of ECH and displacement of its chlorine atoms in a  $\text{NaN}_3/\text{DMF}$ /ethylene glycol or propylene glycol medium ( $\sim 363 \text{ K} = \sim 90^\circ\text{C}$ , 15 h) has also been considered. A drawback of this method is the difficulty to completely remove the non-volatile solvent from the polymer.

The self-heating rate and thermal decomposition of octylazide, GAP-AA-2000 (normal GAP, but OH-end groups as esters of  $\alpha$ -azidoacetic acid), GAP-AA-500 (short chain GAP, but OH-end groups as esters of  $\alpha$ -azidoacetic acid), and GAPA were examined in an accelerating rate calorimeter (ARC) with 6-g samples contained in a titanium bomblet [206].

An acyl-terminated GAP was synthesized via the reaction between 2,4,6-trinitrobenzoyl (TNB) chloride and GAP [207]. The TNB-GAP structure was confirmed by FT-IR, UV-vis,  $^1\text{H}$  NMR, and  $^{13}\text{C}$  NMR. The glass transition temperature ( $T_g$ ) of TNB-GAP was evaluated by DSC, and the thermal stability of TNB-GAP was tested by TGA. DSC traces showed that TNB-GAP had a  $T_g$  of  $227 \text{ K} = -46^\circ\text{C}$ . TGA showed that the thermo-oxidative degradation of TNB-GAP in air was a two-step reaction, and the percentage of degraded TNB-GAP nearly reached 100% at  $923 \text{ K} = 650^\circ\text{C}$ . Non-isothermal DSC results indicated that the apparent activation energies of the two-step exothermic decomposition of TNB-GAP were 80.16 and 162.92 kJ/mol, and the values of the pre-exponential constant were  $1.75 \times 10^{10}$  and  $1.22 \times 10^{16}$ , respectively. Future volumes on solid propellants will contain detailed chapters on use of GAP polymers as energetic binders in solid propellants.

#### 4.7 Azidoacetic Acid

Azidoacetic acid,  $\text{N}_3\text{CH}_2\text{COOH}$ , contains only one azide group, but most of the esters formed with azidoacetic acid and polyols contain more than one azido group. This group of azido compounds that is actively evaluated as energetic plasticizers is discussed in the Section 13 “Polyol Esters of Azidoacetic Acid.”

Azidoacetic acid can be made by irradiating a mixture of 2-chloroacetic acid (0.094 g) and sodium azide (0.072 g) with microwaves for 30 min. [179]. Azidoacetic acid forms esters with alcohols and polyols that are suitable as energetic plasticizers.

## 4.8 Other Aliphatic Monoazides

There are many organic compounds that carry one azido group in addition to several other energetic groups, like nitrate or nitro groups. Azidotrifluoromethane,  $\text{CF}_3\text{N}_3$ , is thermally more stable than azidomethane, methyl azide  $\text{CH}_3\text{N}_3$  [208]. The structure of azidotrifluoromethane has been obtained by a combined analysis of electron diffraction intensities and ground-state rotational constants derived from the microwave spectrum  $\text{C}-\text{F}$  1.328 Å,  $\text{C}-\text{N}$  1.425 Å,  $\text{N}-\text{N}$  1.252 Å,  $\text{N}-\text{N}$  1.118 Å,  $\angle\text{CNN}$  112.4°,  $\angle\text{NNN}$  169.6°,  $\angle\text{FCF}$  108.7°. The  $\text{CF}_3$  group is in the staggered position with respect to the  $\text{N}_3$  group and tilted away from it by 5.8° [209].

Compounds with the general formula  $\text{F}(\text{NO}_2)_2\text{C}-\text{CH}_2-\text{O}-\text{CH}_2-\text{R}$  wherein  $\text{R}$  is  $-\text{CH}_2\text{N}_3$  or  $-\text{O}-\text{CH}(\text{CH}_2\text{N}_3)_2$ , such as 1,3-diazido-2-propyl fluorodinitroethyl formal, azidomethyl fluorodinitroethyl ether, 1,7-diazido-4,4-difluoraminoheptane, or *N*-(trinitroethyl)-*N*-(3-azidopropyl)nitramine can be used as energetic plasticizers for solid propellants [210]. Azidodinitroalkanes where the azido and two nitro groups are located on the same terminal carbon atom can be synthesized by reaction of 1,1,1-trinitroalkyl compounds with lithium azide [211, 212].

Azidodinitromethyl compounds can be prepared by electrooxidative coupling of azide ions to dinitromethyl carbanions. Thus, anodic coupling of sodium azide with ethyl 4,4-dinitrobutyrate produced ethyl 4-azido-4,4-dinitrobutyrate. Similarly, 4-azido-4,4-dinitrobutyl acetate was prepared from 4,4-dinitrobutyl acetate and converted by way of the corresponding alcohol to the nitrate ester, 4-azido-4,4-dinitrobutyl nitrate [213]. 1-Azido-1,1-dinitroethane may be prepared by reacting 1,1,1-trinitroethane with lithium azide and can be used as a monopropellant [214].

Several azidonitrazapropanes and azidonitrazapentanes are described in *Encyclopedia of Liquid Fuels*, chapter “Nitramines.” That chapter includes energetic azido eutectics which can be used as energetic plasticizers, e.g. [215].

2-Methyl-2-nitro-1-azidopropane was synthesized through a condensation reaction, substitution reaction and azidation [216]. The molecular structure of the product was determined by MS, IR, and  $^1\text{H}$  NMR. Thermochemical properties of  $\alpha$ -azidopolynitroalkanes and the energy of  $\text{C}-\text{N}_3$  bond-dissociation in organic azides were derived from experimental data [217].

$\alpha$ -Azidopolynitroalkanes can be prepared by reaction of polynitroalkanes or  $\alpha$ -(difluoroamino)polynitroalkanes with  $\text{NaN}_3$  [218]. In the case of tetranitromethane, one or two nitro groups can be substituted, depending on the reaction conditions. The reaction of 1,1,1-trinitroethane with  $\text{NaN}_3$  affords nitro-1,2,3-triazole, together with 1-azido-1,1-dinitroethane. 3-Azido-2,2-dinitropropanol can be made from a cyclic 2,2-dinitro 1,3-propanediol sulfite with azide, followed by hydrolysis of the sulfate [219].

Azidomethyl-dinitroxydimethyl-nitromethane,  $\text{N}_3\text{CH}_2(\text{O}_2\text{NOCH}_2)_2\text{CNO}_2$ , AMDN-NM, has been evaluated as a plasticizer for double-base propellants [220]. The small-scale explosive sensitivity of neat AMDNNM was determined to be slightly

more sensitive than pentaerythritol tetranitrate (PETN). Neat AMDNNM had thermal stabilities similar to that of PETN.

*n*-Butyl azide,  $C_4H_9N_3$ , CAS RN [7332-00-5], has a refractive index of  $n_D^{20} = 1.4102$  and boils at 344 K at 30 kPa (71 °C at 225 mm Hg) [221]. *n*-Amyl azide,  $C_5H_{11}N_3$ , CAS RN [26330-06-3], has a refractive index of  $n_D^{20} = 1.4266$  and boils at 336.6 K at 13.3 kPa (63.5 °C at 100 mm Hg). 4-Heptyl azide has a refractive index of  $n_D^{23} = 1.4370$  and boils at 351 K at 26.7 kPa (78 °C at 200 mm Hg).

1,3-Diazo-2-propyl trinitropropyl carbamate,  $(O_2N)_3CCH_2CH_2NHCOOCH(CH_2N_3)_2$ , DATC, can be prepared by reaction of 3,3,3-trinitropropyl isocyanate with 1,3-diazo-2-propanol. In a subsequent reaction, DATC can be reacted with nitric acid in acetic anhydride to make a nitramine, 1,3-diazo-2-propyl-*N*-nitro-*N*-trinitropropyl carbamate,  $(O_2N)_3CCH_2CH_2N(NO_2)COOCH(CH_2N_3)_2$ , DANTC which can be used as an energetic plasticizer [222]. The enthalpy of formation of DANTC is +163 kJ/mol (+39 kcal/mol) and its freezing point is 271 K (−2 °C).

#### 4.9 Alkenyl Azides

The structure of alkenyl azides is of interest if there is any interaction between the electron clouds in the C=C double bond and the adjacent N=N bonds. This was investigated by *ab initio* calculations of energy levels and vibrational frequencies of 3-azidopropene (allyl azide) and a comparison of calculated and measured data [223].

3-Azidopropene, allyl azide,  $H_2C=CH-CH_2-N_3$ , CAS RN [821-13-6], was synthesized and the structure and conformational composition studied by electron diffraction from the vapor, IR spectra of the vapor, of the liquid and of the amorphous solid at 90 K, Raman spectra of the cooled liquid and of the amorphous and crystalline solids at 90 K [144]. The normal modes of vibration for the five distinct conformations of 3-azidopropene were calculated using transferred scaled quantum mechanical force fields for propene and azidoethane. Vinyl azides can be incorporated in energetic binders for solid propellants [114].

#### 4.10 Alkynyl Azides

Like the case in alkenyl azides, the structure of alkynyl azides is of interest if there is any interaction between the electron clouds in the C≡C triple bond and the adjacent N=N bonds. Alkynyl azides are more energetic than comparable alkyl azides and can be used for the synthesis of heterocyclic compounds.

3-Azidopropyne was synthesized and the structure was determined by electron diffraction from the vapor and computed by *ab initio* Hartree-Fock self-consistent field (SCF) method calculations [224]. IR spectra of the vapor, of the cooled solid, of the matrix isolated species in argon and nitrogen at 13 K, and of the solid at 90 K were

recorded and Raman spectra of the cooled liquid and of the amorphous and crystalline solid were also obtained. From the spectroscopic investigation it was evident that the title compound exists as only one conformer in all states of aggregation. The electron diffraction results and the theoretical calculations showed unambiguously the conformation to the *gauche* around the C—N bond with a dihedral angle of  $37^\circ$  from *syn* and with the NNN angle of  $169^\circ$  oriented *anti* to the C—N bond.

The IR spectra and Raman of 4-azidobut-1-yne were recorded in the vapor and liquid state and as amorphous and crystalline solids at liquid nitrogen temperature [225, 226]. 4-Azidobut-1-yne can exist in five distinct conformations. IR spectra of the molecule were obtained in the vapor and liquid states at room temperature and as amorphous and crystalline solids at liquid nitrogen temperature [227]. Apparently, all five conformers were present in the liquid at room temperature and in the argon matrix at 12K, whereas only three conformers were observed in the nitrogen matrix. It was not possible to estimate the energy differences between conformers. An isomer of 4-azidobut-1-yne is 4-azidobut-2-yne and the vibrational spectra, molecular structures and conformations of these organic azides were measured and compared [228].

A polymeric polytriazole formed as an insoluble byproduct during the synthesis of propargyl azide from propargyl bromide and sodium azide [229]. It appeared to be a polymer of 4-methylene-1,2,3-triazole.

It has not been possible to isolate azidoethyne (acetylenyl azide),  $\text{HC}\equiv\text{C}-\text{N}_3$  in the pure state, only its reaction products with cyclooctyne, bicyclic compounds, could be found [230]. For instance, the reaction of sodium acetylide with tosyl azide gave only a mixture of two triazoles. The reaction of ethynyl chloride with sodium azide gave only mixtures of triazoles. Attempts to convert a C=C double bond in vinyl azide to a C $\equiv$ C triple bond failed.

#### 4.11 Cyanogen Azide

Cyanogen azide, consisting of only carbon and nitrogen, could be considered an organic or an inorganic compound. It is a very reactive compound and a useful intermediate in the synthesis of a range of other organic compounds. The reactive intermediate is cyanonitrene  $\text{N}\equiv\text{CN}^\cdot$  which readily adds to C=C double bonds or forms ring structures with C $\equiv$ C acetylenic bonds. Cyanogen azide is too sensitive to be used as a rocket propellant, but it is a useful intermediate in the synthesis of other energetic compounds.

Cyanogen azide can be synthesized in nearly quantitative yield by the reaction of sodium azide with cyanogen chloride in aprotic media [231, 232]. Cyanogen azide, a colorless oil, detonates with great violence when subjected to mechanical or thermal shock, and great care must be taken in any work with this compound. It can be handled relatively safely when diluted in solvents. The half-life of a 27% solution of the azide in acetonitrile is days at room temperature, but this solution can be stored

indefinitely without change at 0 to  $-20^{\circ}\text{C}$ . The pure, undiluted azide is too sensitive for combustion analysis or determination of its IR, Raman spectra [233] or microwave spectra [234] or electron diffraction spectra [235], or one must operate at very low pressures. Computer calculations predicted the enthalpy of cyanogen azide vapor to be  $+501.1\text{ kJ/mol}$  [149]. The reaction of cyanogen azide with olefinic hydrocarbons at 273–303 K ( $0$ – $30^{\circ}\text{C}$ ) gives *N*-cyanoaziridines and 1-alkylalkyldenecyanamides [236].

## 5 Aromatic Azides with One Azido Group

Phenyl azide, azidobenzene,  $\text{C}_6\text{H}_5\text{N}_3$ , CAS RN [622-37-7], has a density of  $1.088\text{ g/cm}^3$ , boils at 322 K at 0.67 kPa ( $49^{\circ}\text{C}$  at 5 mm Hg), freezes at 245.6 K ( $-27.5^{\circ}\text{C}$ ) and has an enthalpy of formation of  $+346\text{ kJ/mol}$  ( $+82.7\text{ kcal/mol}$ ) [221]. Phenyl azide is not sufficiently energetic to be used as a monopropellant but could potentially be used as a fuel. Phenyl azide is a yellow oil with a bitter almond-like odor and may explode on heating and the attempt to distil it. One would expect that the reaction of aniline with nitrous acid would give phenyl azide, but of course that reaction forms the phenyldiazonium salt. Phenyl azide can be prepared by reaction of phenylhydrazine with thionyl chloride. Phenyl azide has been prepared by the action of nitrous acid on phenylhydrazine hydrochloride, reaction of ammonia with diazobenzene perbromide and by the reaction between a diazo salt and sodium azide [237].

Photolysis of phenyl azide, a photo-initiated autocatalytic chain decomposition of phenyl azide, leads to ring widening and formation of dehydroazepines. The combustion characteristics of droplets of phenyl azide were examined experimentally [174].

4-Nitrophenyl azide would be more energetic than plain phenyl azide. The enthalpy of combustion of crystalline 4-nitrophenyl azide was determined by static oxygen bomb calorimetry at 298.15 K as  $3241.4 \pm 4.2\text{ kJ/mol}$  [238]. The corresponding enthalpies of formation using an estimated enthalpy of sublimation are  $\Delta H_f^0(\text{C}) = 308.7 \pm 4.3$  and  $\Delta H_f^0(\text{G}) = 389.7 \pm 5.2\text{ kJ/mol}$ .

## 6 Heterocyclic Azides with One Azido Group

There are numerous heterocyclic compounds with one azido group. Most of the heterocyclic compounds with azido and numerous other, potentially explosophoric groups, are described in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic Amines.”

## 7 Aliphatic Azides with Two Azido Groups

There are numerous aliphatic linear azides with additional nitro or nitroxy groups in the molecule. These compounds may already have been covered in the nitro compound or alkyl nitrate chapters, but some of them are reported here in the azide chapter; however, linear aliphatic nitramines with azido groups in the alkyl group are all discussed in the chapter on alkylnitramines.

A series of terminal alkyl diazides in quantities of 200 g was synthesized and characterized by IR and NMR spectra, including 1,3-diazidopropane,  $C_3H_6N_6$ , CAS RN [100910-72-3], 1,4-diazidobutane,  $C_4H_8N_6$ , CAS RN [24345-72-0], 1,5-diazidopentane,  $C_5H_{10}N_6$ , CAS RN [17607-21-5], 1,6-diazidohexane,  $C_6H_{12}N_6$ , CAS RN [13028-54-1], 1,7-diazidoheptane,  $C_7H_{14}N_6$ , CAS RN [98428-99-0] and 1,8-diazidooctane,  $C_8H_{16}N_6$ , CAS RN [98560-17-9] [131]. The report gives some spectra but lacks physical properties of the prepared compounds. Mixtures of 2-azidoethanol or 1,3-diazidopropanol with 1-nitroso-3-nitrazapentane or 1-nitroso-3-nitrazabutane can be used as monopropellants [239].

2-Azidoethanol, 1,3-diazidopropanol, 2,3-diazidopropanol, 1,4-diazidobut-2-ene, dimethyl 2,2-diazidomalonate, 2,3-di(azidomethyl)oxirane, and 1,1,2,2-tetra(azidomethyl)ethane were evaluated as replacements for hydrazine in hypergolic combinations with hydrogen peroxide (HTP) or white fuming nitric acid (WFNA) [182]. The aliphatic azides with two azido groups in the molecule are discussed here in the sequence ordered by the number of carbon atoms in the molecule.

### 7.1 $C_1$ Aliphatic Azides with Two Azido Groups

#### 7.1.1 Methylene Azide

Methylene azide, diazidomethane,  $CH_2(N_3)_2$ , is unstable and it has not been fully characterized. Diazidomethane has been the likely cause of an accidental explosion in a laboratory [240]. A safer method is the use of azide-loaded ion exchange resins which allows the slow, but safe synthesis of diazidomethane and even triazidomethane [241]. When using dichloromethane as a solvent in the synthesis of organic azides, azide ion displaces chlorine from dichloromethane surprisingly rapidly to form diazidomethane, an explosive material [242].

#### 7.1.2 Carbonyl Diazide

Carbonyl diazide (formerly called azidophosgene, carbazoimide),  $OC(N_3)_2$ ,  $M = 112.06$  g/mol, nitrogen content 75.00% N, is a readily subliming solid, crystallizing in long needles that are very soluble in water, ethanol, and ether but insoluble in petroleum ether. In water it undergoes hydrolysis to yield  $CO_2$  and  $HN_3$ . It has a penetrating odor and like other carbonyl compounds (phosgene) is highly toxic

and dangerous. Carbonyl diazide can be prepared by the action of sodium nitrite on the hydrochloride of carbohydrazide, but this reaction did not always proceed homogeneously and hydrazinedicarboxyazide was always formed as a byproduct in ca. 20% yield. The two compounds could be separated by carrying out the diazotization under benzene. Carbonyl diazide may explode violently, even under water, on slightest friction or when exposed to light. Carbonyl diazide converts aromatic hydrocarbons into pyridine bases and into primary amines.

Carbonyl diazide was prepared by reacting  $\text{NaN}_3$  (0.5 mmol) with  $\text{FC(O)Cl}$  (1.4 mmol) in a flame-sealed glass ampule at room temperature for 4 days [243]. Volatile products from three batches were collected and separated by repeated trap-to-trap condensation. The product, ca. 60 mg  $\text{OC(N}_3)_2$ , was retained in the 213 K ( $-60^\circ\text{C}$ ) trap as a white solid. Carbonyl diazide crystallized in the orthorhombic space group  $Pnma$  with four molecules per unit cell. The pure substance showed remarkable kinetic stability at room temperature in the gaseous, liquid, and solid states. Gaseous and liquid  $\text{OC(N}_3)_2$  was found to be stable for 2 weeks at room temperature. A melting point of 289 K ( $16^\circ\text{C}$ ) and vapor pressure of 5.6 mbar at 273 K ( $0^\circ\text{C}$ ) were determined. Two planar conformers were found in the gas phase, and a composition of 12% *anti-syn* versus 88% *syn-syn* conformer in the gaseous equilibrium mixture at room temperature was estimated by matrix IR spectroscopy. In the crystal structure, only the more stable *syn-syn* conformer was observed. The partially reacted, more volatile product  $\text{FC(O)N}_3$  was found in the 173 K ( $-100^\circ\text{C}$ ) trap as confirmed by its IR spectrum.

The minimum energy structure, vibrational frequencies, and thermodynamic properties of carbonyl diazide,  $\text{OC(N}_3)_2$ , have been determined using Gaussian-X compound computational methods [244]. The calculations indicated that carbonyl diazide has a significantly high enthalpy of formation, and its enthalpy of decomposition is commensurate with high energy materials.

## 7.2 $\text{C}_2$ Aliphatic Azides with Two Azido Groups

1,2-Diazidoethane, ethylene azide,  $\text{N}_3\text{CH}_2\text{CH}_2\text{N}_3$ ,  $M = 112.07$  g/mol, nitrogen content 74.97%, can be prepared by reaction of 1,2-dichloroethane with sodium azide in DMF at 333 K ( $60^\circ\text{C}$ ) [245]. The formed diazidoethane can be extracted with ether from water and the extract dried over magnesium sulfate, and the ether evaporated to obtain the pure product.

1,2-Diazidoethane can be made from a mixture of 1,2-dibromoethane (0.187 g) and sodium azide (0.072 g) with microwave irradiation for 30 min. [179]. The melting point reported by these authors ( $198^\circ\text{C}$ ) is totally **in error**. 1,2-Diazidoethane is an oily liquid that has a density of  $1.178$  g/cm<sup>3</sup> and boils at 326 K under a vacuum pressure of 1.2 kPa ( $53^\circ\text{C}$  under a vacuum pressure of 9 mm Hg) [246].

### 7.3 C<sub>3</sub> Aliphatic Azides with Two Azido Groups

1,3-Diazidopropane,  $\text{N}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{N}_3$ ,  $\text{C}_3\text{H}_6\text{N}_6$ , CAS RN [100910-72-3],  $M = 126.12 \text{ g/mol} = 7.929 \text{ mol/kg}$ , is a colorless, clear, oily liquid. 1,3-Diazidopropane has a density of  $1.1042 \text{ g/cm}^3$ , a boiling point of 423 K (150 °C) at atmospheric pressure, a boiling point of 373 K at a reduced pressure of 1.2 kPa (100 °C at reduced pressure of 9 mm Hg), a boiling point of 321–323 K at a reduced pressure of 0.26 kPa (48–50 °C at reduced pressure of 2 mm Hg), and a refractive index  $n_D^{20}$  of 1.4788. Other sources list a refractive index of 1.4729 at 589.3 nm and 293 K (20 °C). It can be mixed with isopropyl nitrate and stored without any reactions. The saturation vapor pressure of 1,3-diazidopropane is 66.7 Pa at 293.5 K, 213 Pa at 313 K and 626 Pa at 333 K (0.5 mm Hg at 20.4 °C, 1.6 mm Hg at 40 °C and 4.7 mm Hg at 60 °C) [247].

1,3-Diazidopropan-2-ol has a density of  $1.2599 \text{ g/cm}^3$  at 293 K, a viscosity of 9.6 cPs at 293 K, and a boiling point of 365 K at 0.4 kPa (92 °C at 3 mm Hg). Its combustion in a strand burner is self-sustaining [248]. Esters of this energetic alcohol with acetic acid and propionic acid have been characterized for their physical properties and burning behavior (Table 9).

2-Nitro-1,3-diazidopropane derivatives were synthesized through a condensation reaction, substitution reaction, and azidation [249]. The molecular structures of the products were then determined by MS, IR, and  $^1\text{H-NMR}$ .

### 7.4 C<sub>4</sub> Aliphatic Azides with Two Azido Groups

High-energy azides containing gun propellants can be prepared using 1,5-diazido-3-nitrazapentane, 1,6-diazido-2,5-dinitrazahexane, 1,7-diazido-2,4,6-trinitrazahexane, or 1,9-diazido-2,4,6,8-tetranitrazanonane [250, 251]. While the compounds listed above are nitramines with  $\text{N-NO}_2$  linkages, similar azidoalkyl compounds with  $\text{C-NO}_2$  linkages, such as 2-methyl-2-nitro-1,3-diazido-propane, 1,3-diazido-2-methyl-2-nitropropane,  $\text{N}_3\text{CH}_2\text{C}(\text{CH}_3)(\text{NO}_2)\text{CH}_2\text{N}_3$ ,  $\text{C}_4\text{H}_7\text{N}_7\text{O}_2$ , NMPA, DAMNP, can also be used as energetic plasticizers [252, 253]. The density of NMPA is  $\rho = 1.28 \text{ g/cm}^3$ , the glass point as determined by DSC is  $T_g = 221.6 \text{ K}$  (−51.5 °C), the onset of thermal decomposition as determined by DSC is 507 K (234 °C), and its impact sensitivity is 34 cm with a 2-kg weight.

1-Azido-2,3-dihydroxy-2-azidomethylpropane, ADMP,  $\text{N}_3\text{CH}_2\text{C}(\text{OH})(\text{CH}_2\text{N}_3)\text{CH}_2\text{OH}$ ,  $\text{C}_4\text{H}_8\text{N}_6\text{O}_2$ , can be made by a five-step synthesis starting with mannitol, acetone, and formaldehyde [254]. ADMP is a colorless oil and has a molecular mass of  $172.15 \text{ g/mol} = 5.809 \text{ mol/kg}$ , an oxygen balance of −92%, a predicted velocity of detonation of 5.69 km/s, a density of  $1.40 \text{ g/cm}^3$ , and an enthalpy of formation of  $+317.1 \text{ kJ/mol} = +1842 \text{ kJ/kg} = +440.4 \text{ kcal/kg}$ . The molecular mass of 156 and oxygen balance of −70% shown in Table 1 of [254] is **incorrect**. DSC indicated that ADMP

undergoes exothermic decomposition in the temperature in the range of 464–533 K (191–260 °C) with heat release of the order of 1390 J/g. ADMP is a potential energetic plasticizer for solid propellants.

2-Methyl-2-nitro-1,3-diazidopropane (NMPA) can be used as a low-molecular weight plasticizer in solid propellants and as an ingredient in gas generants. NMPA was synthesized via a process that consisted of three steps, i.e. condensation, sulfonation and azido-substitution, using nitroethane and formaldehyde as starting materials [252]. The factors affecting the NMPA yield, including reaction temperature, time, and solvent for azido-substitution, were optimized. The optimal reaction conditions were:  $T = 366 - 368 \text{ K} = 93 - 95 \text{ °C}$ ,  $t = 30 \text{ h}$ , medium DMSO, which improved the NMPA yield up to 71.5% (based on nitroethane) with a purity of 99%. The structure of the resulting product was identified by IR, NMR, and elemental analysis. Some properties of NMPA were measured as follows:  $\rho$  1.28 g/cm<sup>3</sup>,  $T_g$ (DSC) 221.6 K = -51.5 °C,  $T_{\text{peak}}$ (DSC) 507 K = 234 °C, impact sensitivity 34 cm with a 2-kg weight.

## 7.5 C<sub>5</sub> Aliphatic Azides with Two Azido Groups

The simplest C<sub>5</sub> diazide is 1,5-diazidopentane, 1,5-pentanediazide, C<sub>5</sub>H<sub>10</sub>N<sub>6</sub>, CAS RN [17607-21-5]. 1,5-Diazidopentane has a density of 1.0600 g/cm<sup>3</sup> at 293 K and a boiling point of 348 K at 0.13 kPa (75 °C at 1 mm Hg) [167].

Property data on several diazides extracted from a summary on methods for preparation and physical properties of linear diazides of the general formula N<sub>3</sub>CHR<sup>1</sup>(CH<sub>2</sub>)<sub>n</sub>CHR<sup>2</sup>N<sub>3</sub> with 5 to 10 carbon atoms are listed in Table 13 [255].

Experimental research to improve the low density and oxygen balance of pure azido compounds has been directed at modified azido compounds, such as azido nitramines, azido nitrate esters, and azido nitro compounds. Experimental methods to obtain compounds with suitable performance can be supported by theoretical calculations. In a theoretical exercise, three azido compounds N<sub>3</sub>(CH<sub>2</sub>)<sub>n</sub>N<sub>3</sub> for  $n = 5, 7, 9$ , and their 27 modified derivatives were examined using density functional theory calculational methods [256]. Results showed that -NNO<sub>2</sub>, -NO<sub>2</sub>, and -ONO<sub>2</sub> all can improve the thermodynamic and energetic properties. The contribution to the thermodynamic properties is -ONO<sub>2</sub> > -NO<sub>2</sub> > -NNO<sub>2</sub> and that to the energetic properties is -NNO<sub>2</sub> > -ONO<sub>2</sub> > -NO<sub>2</sub>. The azido nitramines possess the best energetic properties and azido nitrate esters have the best thermodynamic properties. All these substituents slightly decrease the thermal stability and the azido nitrate esters possess the lowest thermal stability. 1,4-Diazidobut-2-ene was synthesized from 2-buten-1,4-diol via the chloro derivative, 1,4-dichlorobut-2-ene and evaluated as a hypergolic fuel [182].

**Table 13:** Properties of diazidoalkanes of the general formula  $N_3CHR^1(CH_2)_nCHR^2N_3$ .

| <i>n</i> | <i>R</i> <sup>1</sup> | <i>R</i> <sup>2</sup> | Gross Formula                                  | Yield<br>% | Boiling<br>point<br>K | at pressure<br>kPa | Boiling<br>point<br>°C | at pressure<br>mm Hg | <i>n</i> <sub>D</sub> <sup>25</sup> |

Data source: [255]

## 7.6 Pentaerythritol Diazido Dinitrate

Pentaerythritol diazido dinitrate, 2,2-diazidomethyl-1,3-propyleneglycol dinitrate, 1,3-propanediol, 2,2-bis(azidomethyl)-, 1,3-dinitrate, PDADN,  $(N_3CH_2)_2C(CH_2ONO_2)_2$ , C<sub>5</sub>H<sub>8</sub>N<sub>8</sub>O<sub>6</sub>, CAS RN [96915-38-7], is an energetic azido nitrate plasticizer with two —N<sub>3</sub> groups and two —ONO<sub>2</sub> groups. In this book, this compound could also have been included in the chapter on nitrate esters in *Encyclopedia of Oxidizers*, chapter “Nitrate Esters,” somewhere close to PETN.

Pentaerythritol tetranitrate (PETN), monoazidopentaerythritol mononitrate (MAPEMN), diazidopentaerythritol dinitrate (PDADN), triazidopentaerythritol mononitrate (TAPEMN), and tetraazidopentaerythritol (TAPE) were prepared and analyzed for their chemical (XRD, NMR, EA, IR) and energetic properties (DTA/DSC, impact and friction sensitivity) and compared to each other [257]. An interesting trend of decreasing melting points from PETN to the triazide was observed.

### 7.6.1 Preparation of Pentaerythritol Diazido Dinitrate

Conversion of pentaerythritol to the chlorides and reaction with sodium azide is not a good method for synthesis of pentaerythritol azides, because the diazides and triazides are difficult to separate.

Diazido derivatives of pentaerythritol can be prepared by reacting 3,3-bis(azidomethyl) oxetane with inorganic acids such as hydrobromic or nitric acid [258]. The resulting diazido monobromide can be reacted with sodium azide to produce pentaerythritol triazide which can be subsequently nitrated to pentaerythritol triazido mononitrate. The pentaerythritol diazido mononitrate produced by the reaction of nitric acid with the above oxetane can be further nitrated with nitric acid

to produce pentaerythritol diazido dinitrate. This compound was described in the patent as a colorless oil,  $n_D^{22.5} = 1.5161$  but it was later shown that it is a solid at room temperature. These diazido and triazido derivatives of pentaerythritol can be utilized as energetic azido plasticizers per se or can serve as intermediates for the production of such plasticizers.

Pentaerythritol diazido dinitrate (PDADN) was synthesized and characterized [259]. The results showed that PDADN is a crystalline compound at room temperature and melts at 312.7–312.8 K (39.6–39.7 °C), which observation disagreed with the report by Frankel who reported that PDADN is a colorless oil with  $n_D^{22.5} = 1.5165$ .

A study was made of the synthesis, structure and physicochemical properties of pentaerythritol diazido dinitrate [260]. Thermal analysis results confirmed that this kind of plasticizer is beneficial to the thermal stability of double base composite propellants and hexogen, and its application in composite modified double base propellants could improve combustion properties.

The method described in US Pat. 4683086 is a four-step process and takes 40 h. A simplified three-step process used hydrogen bromide in acetic anhydride to make the dibromide instead of the dichloride [261]. The dibromide is then reacted with sodium azide to make the diazide, and the last step is the nitration. This process is not only faster, 6 h instead of 40 h, it also gives a better yield. The melting point of PDADN thus produced was 312–313 K (39–40 °C).

A new technique for preparing PDADN proceeds via bromination reaction of pentaerythritol as starting material, azidation reaction of 2,2-bromomethyl-1,3-propanediol and nitration reaction of 2,2-azido-1,3-propanediol [262]. The structure of PDADN was characterized by IR,  $^1\text{H-NMR}$ , and elemental analysis.

### 7.6.2 Molecular Structure of Pentaerythritol Diazido Dinitrate

The nitroxy and azido groups rotate around the C–N or C–O bond and can be in *trans* or *cis* configurations to each other. Their positions affect the energy and stability of the molecule.

Frankel reported that PDADN is a nearly colorless oil at room temperature, but Wang argued that this compound is a crystalline material with melting point 312.7–312.8 K (39.6–39.7 °C). To clarify this disagreement about liquid or solid state of PDADN at room temperature, the structure of PDADN was studied by means of FTIR, MS, and NMR [263]. The results showed that the structure of PDADN is that of a crystalline solid.

The molecular geometries and electronic structures of the four conformations of PDADN were optimized by using a semi-empirical AM1-MO method [264]. Among the four conformations, the structure with one  $-\text{ONO}_2$  group at *trans* conformation and another  $-\text{ONO}_2$  and two  $-\text{N}_3$  groups at *cis* conformations is the most stable.

The molecular geometries, electronic structures and IR spectra of the four conformations of PDADN were calculated by means of a DFT B3LYP method [265]. Among the

four conformations, the one with structure of one  $-\text{NO}_2$  group at *cis* position and another  $-\text{NO}_2$  group and two  $-\text{N}_3$  groups at *trans* position was predicted to be the most stable. The calculated IR absorption frequencies of  $-\text{NO}_2$  groups and  $-\text{N}_3$  groups were in good agreement with the experimental data.

One of the main applications of PDADN would be as an energetic plasticizer in double-base propellants. Density functional theory and molecular orbital dynamic calculations have attempted to predict interactions of nitrocellulose/nitroglycerin and PDADN during storage in propellants [266].

### 7.6.3 Thermal Decomposition of Pentaerythritol Diazido Dinitrate

Under non-isothermal conditions, the thermal behavior of PDADN was studied using TGA, DSC, pressure DSC and *in situ*/rapid scanning Fourier transform infrared (RSFT-IR) spectroscopy [267]. The results showed that **(1)** the extrapolated onset temperatures ( $T_e$ ), peak temperatures ( $T_p$ ) and enthalpy of decomposition ( $\Delta H_{\text{dec}}$ ) increase with the change of pressure from 0.1 to 2 MPa. Over the range of pressure from 2.0 to 6 MPa, the thermal behavior of PDADN does not seem to be obviously affected by the pressure; **(2)** the apparent activation energy, pre-exponential constant and the most probable integral mechanism function of thermal decomposition of PDADN at a pressure of 0.1 MPa were 134.9 kJ/mol,  $10^{12.7} \text{ s}^{-1}$  and  $1 - (1 - \alpha)^3$ , respectively; **(3)** the experimental values of pressure affected the magnitude of the apparent activation energy; **(4)** the critical temperature of thermal explosive for PDADN was predicted to be 424 K [268].

Pentaerythritol diazido dinitrate thermal decomposition was investigated by DSC-TGA-FTIR by measuring the thermo-infrared (TIR) curves of the change of the IR characteristics relative absorption intensity of decomposition gas products with temperature and time [269]. The non-isothermal kinetics, kinetic parameters and mechanism functions of PDADN decomposition gas products were obtained by using the Coats-Redfern and Ozawa equations. The mechanism of PDADN thermal decomposition was then analyzed based on isokinetic point of the formation rate among all the decomposition gas products.

The combustion and explosion characteristics, thermal stability and mechanical shock and friction sensitivities of PDADN were examined and the results indicated that PDADN has low friction sensitivity and good thermal stability, which would make it suitable as an energetic plasticizer in solid propellants [270].

### 7.6.4 Properties of Other Pentaerythritol Azides

Diazidopentaerythritol  $(\text{HOCH}_2)_2\text{C}(\text{CH}_2\text{N}_3)_2$  and triazidopentaerythritol  $\text{HOCH}_2\text{C}(\text{CH}_2\text{N}_3)_3$  can be used to make tris(2,2,2-triazidomethyl)ethyl esters of carboxylic acids [271]. Triazidopentaerythritol (pentaerythritol triazide) is a colorless oil,  $n_D^{22} 1.5319$ .

### 7.7 Other C<sub>5</sub> Aliphatic Azides with Two Azido Groups

An energetic plasticizer, 1,3-diazido-2-ethyl-2-nitropropane (DAENP), was synthesized by a three-step process **(1)** 1-nitropropane was condensed with formaldehyde to yield 2-ethyl-2-nitro-1,3-propane diol; **(2)** 2-ethyl-2-nitro-1,3-propane diol on tosylation gave 2-ethyl-2-nitro-1,3-bis(p-toluene sulfonyl) propyl ester; **(3)** azidation of the tosylated compound [272]. The product was characterized by elemental analysis, FTIR, and <sup>1</sup>H-NMR, and purity was tested by HPLC. Thermal studies revealed that DAENP is thermally stable up to 469 K (196 °C), has high energy output of the order 2056 J/g, and a very low glass transition temperature (176 K = -96.76 °C). DAENP was compatible with energetic binders like GAP, 3,3'-bis-azidomethyl oxetane-tetrahydrofuran (BAMO-THF) copolymer, and poly-3-nitratomethyl-3-methyl oxetane (NIMMO) or poly nitratomethyl oxetane (PLN).

### 7.8 C<sub>≥7</sub> Aliphatic Azides with Two Azido Groups

1,9-Diazido-2,2,8,8-tetranitro-4,6-dioxanonane, N<sub>3</sub>CH<sub>2</sub>C(NO<sub>2</sub>)<sub>2</sub>CH<sub>2</sub>OCH<sub>2</sub>OCH<sub>2</sub>C(NO<sub>2</sub>)<sub>2</sub>=CH<sub>2</sub>N<sub>3</sub>, C<sub>7</sub>H<sub>10</sub>N<sub>6</sub>O<sub>10</sub>, has been synthesized from bis(trinitroethyl)formal [273].

An azido analog to [H<sub>3</sub>C-C(NO<sub>2</sub>)<sub>2</sub>-CH<sub>2</sub>-O-]<sub>2</sub>CH<sub>2</sub>, bis-2,2-dinitropropyl formal (BDNPF), was synthesized that contained two azido groups instead of two nitro groups, although in different positions from where the vicinal nitro groups are in BDNPF [124]. The synthesis of [(N<sub>3</sub>CH<sub>2</sub>)<sub>2</sub>CH-O-]<sub>2</sub>CH<sub>2</sub>, C<sub>7</sub>H<sub>12</sub>N<sub>12</sub>O<sub>2</sub>, BDPF, started with bis(1,3-dichloro-2-propyl)formal [(ClH<sub>2</sub>C)<sub>2</sub>-CH-O-]<sub>2</sub>CH<sub>2</sub> which was reacted with a metal azide in a solvent and resulted in a yield of 98% and purity of 98%. The optimum reaction conditions were: for condensation reaction, reaction temperature 273–278 K (0–5 °C), 4 mL sulfuric acid as catalyst, ethylene dichloride as solvent; for the azidizing reaction, reaction temperature 368–372 K (95–99 °C), dimethyl sulfoxide as solvent, reaction time 4 h.

Diazidoalkane fuel additives were investigated as a method to improve the performance of LOX/RP-1 booster engines by causing microexplosions of evaporating fuel droplets [274]. Compared with neat RP-1, the azide additives have a higher fuel density and allow an increase in theoretical specific impulse for mixture ratios below 2.6. 1,10-Diazidodecane (DAD) was used for the initial evaluation in four hot fire tests using subscale combustor hardware to determine the effect of diazidodecane on combustion performance. The density of DAD is 20% higher than that of neat RP-1. 1,10-Diazidodecane is a clear liquid and is completely miscible with RP-1.

## 8 Aliphatic Azides with Three Azido Groups

The simplest, and probably the most energetic alkyl azido compound with three azido groups is the triazidocarbenium ion,  $(\text{N}_3)_3\text{C}^+$ , which was synthesized in the form of salts combined with powerful oxidizing anions such as dinitramide, perchlorate, or tetrafluoroborate [275]. The enthalpies of formation of  $(\text{N}_3)_3\text{C}^+\text{N}(\text{NO}_2)_2^-$  and  $(\text{N}_3)_3\text{C}^+\text{ClO}_4^-$  were estimated to be +1054 and +912 kJ/mol (+252 and +218 kcal/mol, respectively), which explains the high explosive power of these salts.

1,1,1-Tris(azidomethyl)ethane (TMETA) can be synthesized from trimethylol-ethane by sulfonation and azide substitution [126]. It was evaluated as a plasticizer for double-base propellants. The structures of the intermediate and the product were confirmed by IR, NMR and elemental analysis. The factors influencing the azide substitution were investigated and under optimized conditions the yield of TMETA could be up to 92.25% and purity 99%. Recommended molar ratio of TMET/ $\text{NaN}_3$  is 4.5/1, temperature 378–383 K (105–110 °C), reaction time 48 h. Some properties of TMETA were measured as density  $\rho = 1.182 \text{ g/cm}^3$ , onset of exotherm in DSC 525.8 K = 252.7 °C, impact sensitivity 31.6 cm with a 2-kg weight.

## 9 Aromatic Azides with Three Azido Groups

Triazidotrinitrobenzene, 1,3,5- $(\text{N}_3)_3$ -2,4,6- $(\text{NO}_2)_3\text{C}_6$ , was synthesized by nitration of triazidodinitrobenzene with either a mixture of fuming nitric and concentrated sulfuric acid or with  $\text{N}_2\text{O}_5$  [276]. Crystals were characterized by single crystal XRD: monoclinic,  $P2_1/c$  (No. 14), with unit cell parameters of  $a = 0.54256(4) \text{ nm}$ ,  $b = 1.8552(1) \text{ nm}$ ,  $c = 1.2129(1) \text{ nm}$ ,  $\beta = 94.91(1)^\circ$ ,  $V = 1.2163(2) \text{ nm}^3$ ,  $Z = 4$ ,  $\rho = 1.836 \text{ g/cm}^3$ . Triazidotrinitrobenzene has a remarkably high density ( $1.84 \text{ g/cm}^3$ ). The standard heat of formation of triazidotrinitrobenzene was computed to be  $\Delta H_f^\circ = 765.8 \text{ kJ/mol} = 2278 \text{ kJ/kg}$ . The predicted detonation properties were  $P = 18.4 \text{ GPa}$  and  $D = 8100 \text{ m/s}$ . The drop weight sensitivity of triazidotrinitrobenzene was compared to that of other organic azides [277].

Triazidobenzenes can be synthesized by the diazotization and azidation reactions of the corresponding triamines. Triazides were considered as potential cross-coupling reagents for polymers, although they did not find wide practical use. Photolysis of triazides and polyazides gives aryl nitrenes which are highly reactive and either lead to ring widening or react with olefinic double bonds [278].

## 10 Organic Azides with Four Azido Groups

### 10.1 Aliphatic Azides with Four Azido Groups

Tetraazidomethane, perazidomethane,  $\text{CN}_{12}$ ,  $\text{C}(\text{N}_3)_4$  is the simplest organic azide with four azido groups in the molecule. Not surprisingly, this compound is extremely sensitive and would be difficult to synthesize.  $\text{CN}_{12}$  is a highly explosive liquid. With a nitrogen content of 93.3%, perazidomethane,  $\text{CN}_{12}$ , is highly explosive but nevertheless isolatable. Tetraazidomethane can be made from commercially available trichloroacetonitrile in one step and undergoes simple dissociation and trapping reactions as well as some more complex transformations [279]. The hydrolysis of tetraazidomethane leads to carbonyl diazide.

Two energetic azido esters derived from bis(1,3-diazido-prop-2-yl)malonic acid and bis(1,3-diazido-prop-2-yl)glutaric acid

Bis(diazidopropyl)malonic Acid

Bis(diazidopropyl)glutaric Acid

have been synthesized and characterized by IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, MS, thermal analysis, and compatibility tests [280, 281]. Both azido esters showed good thermal stability with onset of decomposition temperatures of 507 and 506 K (234 and 233 °C). Their densities were measured to be 1.25 and 1.27 g/cm<sup>3</sup>, respectively. Glass transition temperatures ( $T_g$ ) of the two compounds were 204 and 205 K (−69 and −68 °C). Thermal decomposition kinetics of both compounds was determined by TGA and DSC. The weight loss pattern of both compounds showed two-step decomposition. Both were compatible with energetic binders like GAP, BAMO-THF, and poly NIMMO or PLN. Density functional theory calculations on both compounds predicted positive heats of formations.

Three new  $\alpha,\alpha$ -diazidated azido esters derived from malonic acid were synthesized and characterized resulting in azido compounds which contain up to six azido moieties and are suitable as energetic plasticizers for solid propellants [282].

1,4-diazido-2,3-bis(azidomethyl)butane, 1,1,2,2-tetra(azidomethyl)ethane, 1,1,2,2-tetrakis(azidomethyl)ethane, has been synthesized and tested for its hypergolic ignition with hydrogen peroxide [182].

Three polyazido compounds based on pentaerythritol and its diether or triether have been prepared and characterized as potential energetic plasticizers [283]. The three compounds were:

Compound

|                                  |                                                             |
|----------------------------------|-------------------------------------------------------------|
| I pentaerythrityl tetraazide     | $C(CH_2N_3)_4$                                              |
| II dipentaerythrityl hexaazide   | $(N_3CH_2)_3C-CH_2-O-CH_2-C(CH_2N_3)_3$                     |
| III tripentaerythrityl octaazide | $(N_3CH_2)_3C-CH_2-O-CH_2-C(CH_2N_3)_2-O-CH_2-C(CH_2N_3)_3$ |

Their large positive enthalpies of formation, good thermal stability, low hydrolysis rates, low melting points and ease of preparation makes these azido compounds attractive as energetic plasticizers. Pentaerythrityl tetraazide (1,3-diazido-2,2-bis(azidomethyl)-propane) can be prepared from pentaerythritol in a two-step, one-pot procedure in 85% yield. Pentaerythrityl tetraazide is a solid that melts at 318 K (45 °C). When heated rapidly to 523 K (250 °C), it will detonate with a loud report and a bright flash. Compounds II and III are viscous, low-volatility oils that refused to crystallize even after being kept at dry ice temperature for a while. Compound III burned smoothly when ignited in an open vessel. No room temperature incompatibilities were noted with any of the three azides in contact with AP, AN, cellulose nitrate, trimethylolethane trinitrate (TMETN) or 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX).

Diethers with two oxygen atoms in ether linkages and alkyl groups with varying numbers of  $-CH_2-N_3$  groups can be prepared in a two-step reaction from 1,3-dichloropropan-2-ol, trioxane (polymeric formaldehyde) and sodium azide and can be used as energetic plasticizers [284, 285]. The simplest of these compounds, bis(1,3-diazido-2-propyl)formal,  $(N_3CH_2)_2CHOCH_2OCH(CH_2N_3)_2$ ,  $C_7H_{12}N_{12}O_2$ , is a yellow oil which has a density at 294 K (21 °C) of 1.28 g/cm<sup>3</sup> and a freezing point of 251 K (-22 °C). The predicted enthalpy of formation is +1002 kJ/mol (+239.4 kcal/mol).

A very thorough investigation of a variety of organic azides led to the synthesis and characterization of numerous polyazido compounds, including carbonyldiazide, 2,2-diazidomethyl-3-azido-propanol, a pentaerythritol where all four hydroxyl

groups were substituted by 2,2-diazidomethyl-3-azido-propyl groups in ether form, 1,3-diazido-2-amino-2-azidomethylpropane ("triazide"), triazidomethane, tetrazidomethane, azidomethyldimethylamine, and tris(azidomethyl)amine [286]. The reaction of trichloroacetonitrile with sodium azide gave triazidoacetonitrile and some tetraazidomethane. Tetraazidomethane is very unstable and contains 93.3% N, the highest possible nitrogen content for any organic compound. When trying to identify its structure by reaction with cyclooctyne, only three of the four azido groups reacted, forming tris(triazolooctane)azidomethane. The boiling point of tetraazidomethane was estimated at  $438\text{ K} = 165^\circ\text{C}$ . Adipic acid and *o*-phthalic acid esters of diazidoalkanol can be used as energetic plasticizers [287].

For the synthesis of tri(azidoethyl)amine, starting with triethanolamine, the hydroxyl groups were replaced with azide groups, giving tri(azidoethyl)amine, which can form an azide salt. It can be quaternized, forming tetrakis-(2-azidoethyl)ammonium ions. Many of the new azido compounds were identified by reaction with cyclooctyne.

## 10.2 Aromatic Azides with Four Azido Groups

The reaction of 1,2,4,5-tetrakis(dibromomethyl)benzene, obtained by photochemical bromination of 1,2,4,5-tetrakis(monobromomethyl)benzene, with  $\text{NaN}_3$  in DMF after 3 h at  $353\text{--}363\text{ K}$  ( $70\text{--}80^\circ\text{C}$ ) gave 1,2,4,5-tetrakis(diazidomethyl)benzene [288, 289]. The structure was confirmed by NMR. It detonated easily if struck with a hammer or by scraping with a spatula. Melting point was  $379\text{--}381\text{ K}$  ( $106\text{--}108^\circ\text{C}$ ). It was less stable than 1,2,4,5-hexakis(diazidomethyl)benzene

# 11 Organic Azides with Five or More Azido Groups

## 11.1 Aromatic Azides with Five or More Azido Groups

The most energetic aromatic azide would be hexaazidobenzene, but its synthesis is wrought with problems [290]. It is easier to look at it by computer [291]. A very detailed overview of aromatic and heterocyclic polyazides highlighted their photolysis, which leads to highly reactive nitrenes which were characterized by their ESR spectra [278].

## 12 Cycloaliphatic Azides

### 12.1 Single Ring Cycloaliphatic Azides

The vapor pressure of cyclopentyl azide, azidocyclopentane,  $C_5H_{11}N_3$ , CAS RN [33670-50-71], can be expressed by the equation [140]:

$$\ln P = 264.98/R - 61126.15/RT - \frac{66.6}{R} \times \ln(T/298.15)$$

where  $P$  is the vapor pressure in Pa,  $T$  is the temperature in kelvin, and  $R$  is the gas constant  $8.3143 \text{ J K}^{-1} \text{ mol}^{-1}$ . This equation translates into a normal boiling point of 416 K ( $143^\circ\text{C}$ ). The heat of vaporization of cyclopentyl azide at 298.15 K is 41.27 kJ/mol.

The heats of combustion of liquid cyclopentyl and cyclohexyl azides are 3433 kJ/mol (820.48 kcal/mol) and 4042 kJ/mol (965.96 kcal/mol), respectively [292]. This corresponds to standard enthalpies of formation of +179.1 kJ/mol (+42.81 kcal/mol) and +108.4 kJ/mol (+25.92 kcal/mol). The densities are 0.9789 and 0.9855 g/cm<sup>3</sup>, respectively.

The enthalpies of formation and densities of two cycloalkyl azides are listed in PEPCODED.DAT: Cyclohexyl azide,  $C_6H_{11}N_3$ ,  $M = 125.18 \text{ g/mol}$ ;  $\Delta H_f = +207 \text{ cal/g} = +25.9 \text{ kcal/mol} = +108.4 \text{ kJ/mol} = +866 \text{ J/g}$ ;  $\rho = 0.0356 \text{ lb/in.}^3 = 0.9854 \text{ g/cm}^3$ ; Cyclopentyl azide,  $C_5H_9N_3$ ,  $M = 111.15 \text{ g/mol}$ ,  $\Delta H_f = +385 \text{ cal/g} = +42.8 \text{ kcal/mol} = +179 \text{ kJ/mol} = +1611 \text{ J/g}$ ;  $\rho = 0.0353 \text{ lb/in.}^3 = 0.9771 \text{ g/cm}^3$ . Cyclohexyl azide has a refractive index of  $n_D^{20} = 1.4693$  and boils at 345 K at 4 kPa ( $72^\circ\text{C}$  at 30 mm Hg) [221].

A new method for preparation of vicinal diazides starting with alkenes was developed and used for the synthesis of 1,2-diazidocyclopentane and 1,2-diazidocyclohexane. The following cycloaliphatic diazides were prepared and their IR and NMR spectra were measured [134]: cyclopentane, 1,2-diazo-, 1,2-diazidocyclopentane,  $C_5H_8N_6$ , CAS RN [141649-36-7]; cyclohexane, 1,2-diazo-, 1,2-diazidocyclohexane,  $C_6H_{10}N_6$ , CAS RN [26593-33-9], with a boiling point of 345–347 K at reduced pressure of 66.7 Pa ( $72\text{--}74^\circ\text{C}$  at reduced pressure of 0.5 mm Hg); and its isomer cyclohexane, 1,4-diazo-, 1,4-diazidocyclohexane,  $C_6H_{10}N_6$ , CAS RN [141649-37-8]. This report gives a few IR and NMR spectra of azides prepared, but no other physical properties.

In analogy to 2-azidoethanol and dimethylaminoethylazide (DMAZ), which have been extensively studied as potential rocket propellants, it would be more energetic to synthesize cycloaliphatic amino azides. In support of experimental efforts to make energetic azido compounds, quantum chemical calculations using a density functional theory method and charge density analysis of amine azide-based propellants (DMAZ, 2-azidoethylhydrazine, 2-azido-*N,N*-dimethylcyclopropanamine, 2-azido-*N*-methylcyclobutanamine, and 2-azidocyclopentanamine) were carried out to understand the geometry, bond topological, electrostatic, and energetic properties [293]. The electron density distribution of these molecules revealed the nature of chemical bonding in these molecules.

## 12.2 Bridged Polycyclic Cycloaliphatic Azides

Two of the more unusual aliphatic azides were prepared by the method referenced above, starting with norbornene. These were 2,3-diazido-bicyclo[2.2.1]heptane,  $C_7H_{10}N_6$ , CAS Registry Number [141649-38-9]

and its dimer, 2,3,6,7-tetraazido-dodecahydro-1,4:5,8-dimethanobiphenylene,  $C_{14}H_{16}N_{12}$ , CAS Registry Number [141649-40-3]

## 12.3 Caged Ring Cycloaliphatic Azides

1,4-Diazidomethylcubane was synthesized by a four-step procedure [221, 294]:

The enthalpies of formation for a series of polyazidocubanes were calculated by using density functional theory (DFT), Hartree-Fock and MP2 methods as well as semi-empirical methods [295]. There exists group additivity for the enthalpies of formation with respect to the azido group. It was found that the enthalpies of formation increased 330–360 kJ/mol for each additional increment of the number of azido groups being added to the cubane skeleton. The predicted detonation velocity of heptaazido and octaazido derivatives was over 9 km/s, and the detonation pressure was ca. 40 GPa.

## 12.4 Other Organic Azides

Azidoacetonitrile, azidoethanenitrile,  $\text{N}\equiv\text{C}-\text{CH}_2-\text{N}_3$ ,  $\text{N}_3\text{CH}_2\text{CN}$ ,  $\text{C}_2\text{H}_2\text{N}_4$ , CAS RN [57707-64-91],  $M = 82.07 \text{ g/mol}$ , contains two explosophoric energetic groups attached to a simple methane molecule. It boils at 326 K at 1.6 kPa (53 °C at 12 mmHg). The compound slowly polymerizes even when kept at 243 K (−30 °C), but it is more stable during storage than the isoelectronic 3-azidopropyne. The heat of evaporation of azidoacetonitrile at 298 K is  $52.58 \pm 0.19 \text{ kJ/mol}$ . The vapor pressure of azidoacetonitrile can be calculated from the equation [140]:

$$\ln P = 278.13/R - 68980.05/RT - \frac{55.0}{R} \ln(T/298.15)$$

where  $P$  is the vapor pressure in Pa,  $T$  is the temperature in kelvin, and  $R$  is the gas constant  $R = 8.3143 \text{ J K}^{-1} \text{ mol}^{-1}$ . This equation translates into a normal boiling point of 423 K (150 °C), which is a very high boiling point for a molecule that contains only one carbon atom.

Matrix-isolation FTIR spectra of azidoacetonitrile and azidoacetone ( $\text{N}_3\text{CH}_2\text{COCH}_3$ ) in solid neon, argon, or nitrogen were recorded and compared to calculated IR spectra using a density-functional theoretical method [296].

## 13 Polyol Esters of Azidoacetic Acid

Azidoacetic acid,  $\text{N}_3\text{CH}_2\text{COOH}$ , can form esters with a wide range of polyols that have low vapor pressure and can serve as energetic plasticizers.

The simplest member of this group is ethylene glycol di(azidoacetate),  $\text{N}_3\text{CH}_2\text{COOCH}_2\text{CH}_2\text{OOCCH}_2\text{N}_3$ ,  $\text{C}_4\text{H}_8\text{N}_6\text{O}_4$ ,  $M = 204.15 \text{ g/mol} = 4.898 \text{ mol/kg}$ . It has a density of  $1.00 \text{ g/cm}^3$ , an oxygen balance of −100% and an enthalpy of formation of  $-80.0 \text{ kJ/mol} = -392 \text{ kJ/kg}$ . A17, an azidoacetic acid ester-based substance, is a product of ICT in Germany. It has the ability to significantly lower the glass transition temperature of other plasticizers.

Ethylene glycol di(azidoacetate), EGBAA, A17

Prime candidates in this category of esters of azidoacetic acid are ethylene glycol bis(azidoacetate) (EGBAA), diethylene glycol bis(azidoacetate) (DEGBAA), trimethylolnitromethane(triazidoacetate) (TMNTA) and pentaerythritol tetrakis(azido-

acetate) (PETKAA) [297]. They are liquid and the glass transition temperatures are between 202.3 and 239 K (−70.8 and −34.1 °C) and have an acceptable thermal stability for practical applications.

Diethylene glycol bis(azidoacetate), DEGBAA

Trimethylolnitromethane(triazidoacetate), TMNTA

Pentaerythritol tetrakis(azidoacetate), PETKAA

Physical properties of these low-volatility compounds suitable as energetic plasticizers are listed in Tables 14 and 15 below.

As two examples, azido esters 1,3-bis(azidoacetoxymethyl)-2-ethylpropane (I)  $\text{N}_3\text{CH}_2\text{COOCH}_2\text{C}(\text{N}_3\text{CH}_2\text{COOCH}_2)(\text{C}_2\text{H}_5)\text{CH}_2\text{OOCH}_2\text{N}_3$ ,  $\text{C}_{10}\text{H}_{17}\text{N}_9\text{O}_6$ , and 1,3-bis(azidoacetoxymethyl)-2,2-bis(azidomethyl)propane (II),  $\text{N}_3\text{CH}_2\text{COOCH}_2\text{C}(\text{N}_3\text{CH}_2)_2\text{CH}_2\text{OOCH}_2\text{N}_3$ ,  $\text{C}_8\text{H}_{12}\text{N}_{12}\text{O}_4$ , have been synthesized and characterized by IR, NMR, and elemental analysis [298]. Thermal studies revealed that both azido esters are thermally stable up to 453 K (180 °C) and their glass transition temperatures are 226 and 221 K (−47 and −52 °C), respectively.

Terminally azido functionalized dendritic esters have been synthesized from a commercially available dendritic polyol [299]. Structural features were confirmed by IR,  $^1\text{H}$  NMR, and elemental analysis. The DSC analysis showed an acceptable thermal stability for practical applications in high energy material formulations.

Azido-terminated dendritic esters have been synthesized by four step processes and the final products and the intermediates were characterized by IR,  $^1\text{H}$  NMR, and elemental analysis [300]. Thermal studies revealed that these dendritic esters were thermally stable up to ~463 K (190 °C) and the glass transition temperatures were found to be 219 and 241 K (−54 and −32 °C), respectively.

**Table 14:** Properties of azidoacetic acid esters.

|                                       | EGBAA   | DEGBAA  | TMNTA   | PETKAA |

# Boranes

## Introduction

Boranes share many properties, such as pyrophoricity, with their alkylated derivatives, the organic boranes described in *Encyclopedia of Liquid Fuels* chapter “Alkylboranes.” Their parent element, boron, is described in chapter “Boron.” Boranes, alkylboranes and elemental boron all share the common disadvantage of diboron trioxide deposition in the combustion products, possibly leading to clogged orifices and nozzle throats.

## 1 Boranes

For a brief period of about 10 years in the 1950s, the chemistry of boron compounds received a substantial amount of attention as a result of the proposed use of boranes and alkylboranes as fuels in air-breathing jet engines. This activity was often mistaken for a rocket propellant program, when actually it was intended primarily for air-breathing jet engines and ramjets. However, while the production base for boron chemicals was being expanded, the potential use of boranes and alkylboranes as rocket propellants was also examined at the same time. The closest alkylboranes have come to being actually used in rocket engines has been in mixtures with triethylaluminum for the hypergolic start and restart of bipropellant engines with LOX as the oxidizer. This practical and important use continues to this day and is a direct benefit of borane chemistry research done in the 1950s, which is reviewed in this chapter.

Other than this particular and only currently active application of alkylboranes, this chapter is not part of a book on modern rocket propellants, but a chapter on the history of rocket propellants. It is very unlikely that boranes will ever again be tested as rocket propellants. This chapter is mostly a *déjà vu* of what has been done in the past.

When it comes to writing a book about boron chemistry, the author has nostalgic memories about the time when, thrilled by the prospect of working with new pyrophoric rocket propellants, he worked as a summer intern student at the Max Planck Institut für Kohleforschung in Germany in 1959 under the direction of Nobel laureate Dr. Karl Ziegler and Dr. Roland Köster. During this time he enthusiastically (but very carefully) learned the safe handling of pyrophoric liquids such as triethylaluminum and the preparation of triethylborane and diethyldiborane in glass apparatus. Each time, when disassembling the apparatus after completion of a synthesis under a flow of inert argon blanketing gas, the disassembling was always a display of fireworks as soon as air was admitted to the few droplets of boranes still clinging to the glass tub-

ing pulled from the apparatus. This voluntary, unpaid summer work was done in the idealistic expectation of the author that some of these compounds could some day in the future be used as rocket propellants. At that time, Ziegler's research institute, close to the author's home town, had the world's largest triethylaluminum production facility to support the fledgling low-density polyethylene catalyst industry using the Ziegler-Natta process, a very lucrative undertaking for the institute and its director. On the loading dock of the institute there were rows and rows of metal drums filled with triethylaluminum waiting to be shipped to the polyethylene manufacturers. That was before the chemical industry assumed the role of supplying triethylaluminum to the polyethylene makers. The author walked in between these drums on the loading dock with mixed feelings, knowing what could happen if one of these drums accidentally started leaking and caught fire (you cannot extinguish burning triethylaluminum with water, it makes things worse).

A detailed write-up in book format of the US borane effort covering the years from 1950 to 1965 is the most comprehensive summary ever published on this exciting period of borane fuel development [1]. An anecdotal and historical account of the US boranes program, written by an insider old-timer, was published later and makes very entertaining reading [2]. We wished similar easy-to-read books had been written on the history of some of the other rocket propellants, such as the early years of hydrazines.

Half a century later, the chemistry of boron compounds still benefits from the boost it received when all of a sudden their potential as high-caloric-value fuels for air-breathing jet engines was realized. This book at hand is a book on rocket propellants, not a book on fuels for air-breathing engines, but we include some information on selected jet engine fuels that may also be of interest as rocket propellants or as fuels and ignition fluids in ramjets and scramjets. The high heat of combustion makes these boron compounds attractive as fuels in air-breathing engines. As we already know, a high heat of combustion alone is not necessarily a criterion for a good rocket propellant if the average molecular weight of the exhaust products is too high or if the exhaust products include condensed phases such as  $B_2O_3$ . In the case of air-breathing turbo jet engines with rotating parts, the deposition of boron oxide(s) as a condensed phase slag in the exhaust caused substantial problems with rotary machinery in turbojets and afterburners, and the project was eventually abandoned with substantial investments in facilities being idled and dismantled because the slag deposition problems could not be solved [3]. Some work on boranes as ramjet or afterburner fuels continued even after the work with turbojets was canceled. Ramjets and afterburners are less susceptible to clogging and erosion of sensitive moving parts by solid exhaust products than turbojets. Throughout this period of exuberant borane enthusiasm, several organizations studied the use of boranes and alkylboranes as rocket propellants (as opposed to jet engine fuels), but none of these studies lead to any practical flight applications of boranes as the main fuels for rockets.

The element boron itself has also been tested as a fuel in solid propellants, ram-air rockets, gelled liquid slurries, and hybrid fuel grains. Of course a large amount of elemental boron goes into making potassium nitrate/boron igniters, which are used in many solid propellant rockets, pyrotechnic devices and airbag inflators.

A long time after the interest in boranes as jet engine fuels and rocket propellants had subsided, the interest in boron hydrides has recently been revived because of their potential to serve as dihydrogen storage media. The hydrogen economy is dependent on efficient hydrogen storage methods, more efficient and compact than compressed hydrogen and easier to handle than liquid hydrogen. Hydrogen gas at high pressure will adsorb reversibly on certain boron hydrides, can then be released on demand, and in this way can be used as a light-weight portable source of energy for combustion machines or fuel cells (see Section 6.6.6). Some of the boron hydride hydrogen storage chemistry used now is based on the extensive borane work of the 1950s. The inorganic boranes are discussed here first, followed by organic borane adduct compounds.

There are at least 12 known boron hydrides, but of all these only three boranes are of interest as rocket propellants: diborane  $B_2H_6$ , pentaborane  $B_5H_9$ , and decaborane  $B_{10}H_{14}$ . Many other boron hydrides have been observed only as short-lived intermediates during transitions between the various boron hydrides, e.g., by pyrolysis.

Proposals for the use of these boranes as rocket fuels published in the 1950s and 1960s were overly optimistic and in the end the toxicity and the problems with boron oxide in the exhaust were insurmountable. In spite of these problems, many static tests with boranes in rocket engines have been conducted, but none of these engines has ever flown in a rocket. Boron oxide as a condensed phase in the two-phase exhaust causes a loss of exhaust velocity. Oxide slag deposits on the injectors and throats cause clogging and reduced heat transfer for cooling. The high heat of combustion of boranes would only be beneficial in the presence of a fuel with lots of hydrogen or possibly fluorine. Thus various fuel mixtures of boranes with other fuels have been tested as rocket propellants. However, boranes react with many of the other known fuels. The best compatibility and solubility would be with hydrocarbon fuels such as kerosene.

Boranes are well suited as fuels for fluorine or fluorine compounds as oxidizers because boron trifluoride is volatile and does not cause the same clogging and condensed exhaust particles problems as  $B_2O_3$ . But of course, boron trifluoride is more toxic than boron oxide.

The current section is an introduction to boranes as a family of chemical compounds. This section is followed by several sections on specific boranes, starting with diborane. This chapter concludes with sections on complex boron hydrides and borane Lewis salt adducts. Alkylboranes are now in a chapter by themselves and can be found in *Encyclopedia of Liquid Fuels*, chapter "Alkylboranes."

## 1.1 Literature Summaries on Boranes

Many chemists have made a lifelong career of studying mostly boranes, resulting in a flood of publications, and some have even received Nobel prizes for their work. There are many books dealing exclusively with boranes and other boron hydrides. Only a few are referenced here, not a complete list of what is available in the libraries, and probably many other books should be listed here, so our apologies to any of authors we may have missed [1, 4–8]. Other books on hydrides include chapters on boranes [9].

There are chapters on boranes in several encyclopedias, standard resources for chemical information where one would look first, such as those authored by Schubert [10], Brotherton et al. [11], and Fedoroff [12]. In addition to books, there are summary reports on the history of boranes that may also be very comprehensive, but not as formal as bound books [13–15]. These summary reports lost their actuality very quickly because progress in this field of high-calorie fuels was so quick during the 1950s and 1960s. In the periodical literature, several surveys on boranes have been compiled and updated at times [16–18]. The chemistry of the lower boron hydrides was reviewed in several publications [19, 20].

The nomenclature for hydrocarbons is fairly strict and well established and most chemists adhere to it. In comparison, unfortunately the nomenclature for boranes, being of a more recent origin, is less well known and many chemists ignore it and continue to use obsolete trivial names [21–24]. Additional prefixes were introduced to differentiate between closed and non-closed borane structures. Admittedly, this author has not checked his writings for consistency and compliance with the latest IUPAC nomenclature guidelines either.

## 1.2 Thermodynamic Properties of Boranes

In 1998, NIST published a compilation of published experimental and computational reports (containing 191 literature references) on the structures, vibrational frequencies, molar enthalpies of formation and standard entropies for 26 gas phase boranes and their fragments for the temperature range 0 to 1500 K [25]. The thermochemical properties were collated via standard programs and listed in tabular format (Table 1). The tabulated values were curve-fitted to standard seven-parameter (NASA CEA) polynomials to facilitate the computation of enthalpies of formation, entropies, and heat capacities for modeling purposes. The equilibrium compositions of the gas phase were calculated, constrained to constant temperature and volume, for several boron-hydrogen (B/H) ratios typical for existing boranes, at various temperatures and pressures. The results indicated that thermodynamic equilibrium was not attained in any of the reported gas-phase kinetics studies, even though the measured concentration profiles appeared to extrapolate to steady-state product distributions. The report lacks data for boranes in other than the gaseous state.

**Table 1:** Thermodynamic data of gaseous boranes and their fragments at 298.15 K and 1 bar.

### 1.3 Chemistry of Boranes

Boranes are Lewis acids and ammonia, amines, and hydrazines are Lewis bases. Lewis acid-Lewis base reactions can be quite energetic, and the heat of reaction can lead to self-ignition. It is unusual to have a hypergolic rocket propellant combination such as pentaborane and hydrazine that consists of two fuels instead of an oxidizer and a fuel. The driving force behind this hypergolic reaction is the high enthalpy of formation of boron nitride, a solid reaction product.

Most boranes are pyrophoric in air and susceptible to hydrolysis, so working with boranes required exclusion of air and moisture, and use of a blanketing, inert gas atmosphere in all storage containers.

## 1.4 Toxicity of Boranes

All boranes are highly toxic [26, 27]. Clinical tests have been developed to detect toxic effects of borane exposure [28, 29]. Sections on toxicity dealing specifically with only one compound at a time are included in all of the following sections on specific boranes.

## 2 Diborane

Diborane, also known as diborane(6), diboron hexahydride,  $(\text{BH}_3)_2$ ,  $\text{B}_2\text{H}_6$ , CAS RN [19287-45-7], is the starting point for the synthesis of all other boranes. Diborane was produced in large quantities when the borane fuels project was in full swing in the US during the 1950s. Diborane is now consumed primarily by the electronics industry as a dopant in the production of silicon wafers for use in semiconductors.

A very comprehensive summary on all aspects of diborane was published in the form of a *Diborane Handbook* by Rocketdyne in 1970 [30]. This is the most detailed handbook on any rocket propellant available in the open literature. If similar handbooks were generally available on all other rocket propellants discussed in our book, then our book would no longer be necessary. We have allowed ourselves to extract a substantial amount of information from that handbook and reformat it for the book at hand.

### 2.1 Production of Diborane

#### 2.1.1 History of the Production of Diborane

The production of diborane is possible using a variety of different methods [31]. Diborane was first isolated as a pyrolysis product of tetraborane, prepared by acid hydrolysis of magnesium boride. In 1931, Schlesinger and Burg prepared diborane by passing hydrogen and boron trichloride through an electric discharge. In about 1944, the first essentially quantitative process for preparing diborane was developed by Schlesinger and Brown. It used lithium hydride to reduce boron trifluoride in diethyl ether. This method was later used by Callery to prepare the first commercial quantities of diborane in the 1950s. In 1947, Hurd prepared diborane by passing a stream of boron halide and hydrogen through catalytic beds of active metals. Several methods using sodium borohydride were later developed. The method preferred involved the reaction of sodium borohydride with boron fluoride in the dimethyl ether of diethylene glycol.

The history of the first production of diborane on an industrial scale is described in the anecdotal book by Dequasie [2]. It is regrettable that there are only a few first-hand accounts of pioneering rocket or jet engine fuel development work during the period of the Cold War. This book is one and there is something to be learned from them. Dibo-

rane is the starting reactant for production of all other boranes. Diborane is the most important intermediate in the production of other boranes. Pentaborane and decaborane are produced by pyrolysis of diborane. When the US started the large-scale production of borane fuels in the 1950s, 90% of the installation costs were for the production of diborane. See also publications by Gould [32], Herrick et al. [33], and Major [34].

### 2.1.2 Reactions for the Production of Diborane

One of the methods used for the industrial synthesis involved the reduction of  $\text{BF}_3$  with sodium hydride [35]:

Either sodium hydride or lithium hydride can be used for the reduction. Lithium hydride as a fine powder suspended in ether reacts on heating with the ether adduct compound of boron trifluoride with the slow evolution of diborane. Two laboratory methods start from boron trichloride with lithium aluminum hydride or from boron trifluoride ether solution with sodium borohydride. Both methods yield only up to 30% of diborane:

It is more convenient to use the ether addition compound of boron trifluoride with ether  $\text{BF}_3 \cdot \text{Et}_2\text{O}$ , which may achieve a yield of diborane of 70–80%. Another convenient method for preparing diborane is the reaction of the addition complex of ether and boron trifluoride with lithium or sodium tetrahydroborate:

If sodium tetrahydroborate is used, the preferred solvent is diglyme (the methyl ether of diethylene glycol). Older methods entail the direct reaction of borohydride salts such as sodium borohydride with a non-oxidizing, non-volatile acid, such as phosphoric acid or dilute sulfuric acid, with the solid sodium borohydride suspended in an inert fluid to better control the heat release and achieve uniform mixing [36–38]:

Another small-scale synthesis method uses potassium tetrahydroborate and phosphoric acid as starting materials [39].

Diborane contaminated with  $\text{SO}_2$  is obtained by the action of sulfuric acid on sodium borohydride, but when the sulfuric acid is replaced by methanesulfonic acid, diborane is obtained in 76% yield free from  $\text{SO}_2$ .

A pilot plant consisting of three independent production units was constructed for the preparation of diborane according to the following equation [40]:

A total of 4.2 kg of diborane of about 95% purity was prepared in 47 runs with an overall yield of 90.9% based on the lithium borohydride. The production unit was built

essentially of all glass and consisted of a reactor connected to cold traps for purification and transfer of the product. The diborane is obtained in an ether solution and has to be fractionated to obtain the pure product. The vapor-phase equilibrium of the diborane-diethyl ether system must be known to achieve effective separation [41].

Oxidation of borohydride salts leads to diborane and that is a convenient method for small-scale preparations:

Passing a mixture of boron tribromide with an excess of hydrogen through an electric arc discharge forms diborane, which can be separated from unreacted boron tribromide and higher boranes by fractionated distillation [42]. Diborane may be purified from contaminants that do not react with pyridine by forming the solid, insoluble borane-pyridine adduct.

A process that starts out with cheap raw products and avoids the use of metal hydrides is the silver-catalyzed hydrogenation of boron trichloride and the disproportionation of the dichloroborane thus formed [43]. A pilot plant based on this process was operated for a while and experience was accumulated for the design of a large-scale plant.

Diborane can be prepared by reacting calcium borohydride with a boron halide in the presence of an inert solvent for calcium borohydride [44]. This reaction may be combined with the reaction of calcium hydride with  $\text{B}_2\text{H}_6$  in two-step cyclic processes for the production of further quantities of  $\text{B}_2\text{H}_6$  or  $\text{Ca}(\text{BH}_4)_2$ . To produce further quantities of  $\text{B}_2\text{H}_6$  the reactions are:

and this cycle may be repeated. Another method for the production of diborane is the high-pressure hydrogenation of alkyl boron compounds [45].

### 2.1.3 Purification of Diborane

Depending on the method how it was prepared, diborane may contain contaminants that interfere with its intended application. In particular, diborane intended for semiconductor processing must be of very high purity. Various methods for the purification of diborane have been recommended.

Diborane  $\text{B}_2\text{H}_6$  can be synthesized by the reaction of  $\text{BF}_3$  with  $\text{KBH}_4$ . Unreacted  $\text{BF}_3$  and/or  $\text{CO}_2$  contaminants can be removed from  $\text{B}_2\text{H}_6$  by contacting the mixture with an alkali metal hydroxide such as  $\text{LiOH}$  [46].

Diborane can be purified by low-temperature fractional distillation [47]. See also [48]. Diborane can be purified by adsorption of impurities and continuous distillation [49, 50].

## 2.2 Physical Properties of Diborane

At room temperature diborane  $B_2H_6$  is a colorless gas that can be liquefied and condensed below 180.6 K ( $-92.5^\circ\text{C}$ ).

The physical properties of diborane were measured repeatedly with great accuracy because this compound is important as an intermediate for the production of other boranes and for semiconductor processing. Summaries of physical properties of diborane were published in [51, 52] and are listed in Table 2.

**Table 2:** Physical properties of diborane.

|                                                             | SI units                                          | Other units                                                       | References |

Data Source: Unless otherwise identified, the data in this table were taken from a Callery product data sheet that is no longer available.

The effort in the US in the 1960s to develop high-energy space-storable bipropellant combinations for challenging deep space missions with high total impulse requirements, such as those to outer planets or comets, has resulted in a series of summary publications in support of the on-going experimental effort to bring diborane as a fuel closer to full-scale use, where it would have been used in upper stages and kick stages with fluorine oxidizers [55, 56].

### 2.2.1 Freezing Point and Phase Diagrams of Diborane

Although a data sheet from Callery gave a freezing point of diborane of 108.29 K = -164.86 °C, other sources listed it as 107.7 K = -165.5 °C [55].

### 2.2.2 Boiling Point of Diborane

Based on vapor pressure measurements, the normal boiling point of diborane is 180.59 ± 0.04 K [57]. The average of four literature boiling points of diborane was 180.65 K = -92.53 °C [55]. A very accurate measurement of the boiling point gave 180.32 K [58].

### 2.2.3 Vapor Pressure of Diborane

According to [58], the vapor pressure below normal boiling point can be calculated from:

$$\log P = 8.110 - \frac{870.95}{T} - 2.221 \times 10^{-3} T$$

and the vapor pressure between normal boiling point and critical point can be calculated from [59]:

$$\log P = 8.1251 - \frac{870.68}{T} - 2.339 \times 10^{-3} T$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. From the latter equation, the normal boiling point of diborane is predicted to be 180.6 ± 0.2 K.

Within the range 151 to 220 K, the vapor pressure data were fitted by the equation [57]:

$$\log P = 3.8262 - \frac{598.3}{T} - \frac{1.6733 \times 10^4}{T^2}$$

where  $P$  is the pressure in atm and  $T$  is the temperature in kelvin. Within the range 151–288 K, the data were fitted by the equation:

$$\log P = 4.8600 - \frac{1236.2}{T} + \frac{1.2215 \times 10^5}{T^2} - \frac{1.2247 \times 10^7}{T^3} + \frac{3.4141 \times 10^8}{T^4}$$

where  $P$  is the vapor pressure in atm and  $T$  is the temperature in kelvin. For the temperature range 108–150 K, the vapor pressure of diborane can be represented by the equation [60]:

$$\log P = 6.9881 - \frac{674.82}{T - 15.02}$$

and for the higher temperature range 150–181 K it can be represented by the equation:

$$\log p = 6.81885 - \frac{583.120}{T - 24.63}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The boiling point of diborane derived from these equations would be  $180.63 \pm 0.02$  K, and the heat of vaporization at the normal boiling point would be 14.28 kJ/mol (3.413 kcal/mol). Two melting points were found for diborane:  $108.14 \pm 0.02$  K and  $108.30 \pm 0.02$  K. The first value is probably that of a metastable phase. No phase transitions were observed in the solid.

An older source obtained the following simple vapor pressure equation [52]:

$$\log p = 7.185 - \frac{782.8}{T}$$

where  $p$  is the pressure in mm Hg and  $T$  is the temperature in kelvin.

The vapor pressure of diborane within the range 118.3–180.8 K can be calculated from an Antoine equation [53]:

$$\log P = 3.78156 - \frac{598.39}{T - 22.175}$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. Several of the above referenced data sources were combined and least-square curve-fitted by the equation [30]:

$$\log P = 3.9426 - \frac{642.99}{T - 17.5}$$

where  $P$  is the vapor pressure in atm and  $T$  is the temperature in kelvin. The curve in Figure 1 was calculated using this equation. Presumably, this averaging of results from different methods would give the most reliable data.

Deuterodiborane is useful to explain the nature of the hydrogen bridge bond and for kinetic and mass spectroscopic studies of diborane conversions. Perdeuterated diborane and lithium borodeuteride are useful sources of deuterium that is needed for chemical lasers. The vapor pressure of deuterodiborane differs substantially from that of the normal hydrogen diborane [61]:

$$\text{B}_2\text{H}_6 \quad \log P = -\frac{974.156}{T} - 0.00653809 T + 9.45290$$

$$\text{B}_2\text{D}_6 \quad \log P = -\frac{962.893}{T} - 0.00601480 T + 9.31798$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

**Figure 1:** Vapor pressure of diborane. (Reproduced and modified from [30].)

### 2.2.4 Density and Partial Molar Volumina of Diborane

Density data of liquid diborane are listed in Table 3.

**Table 3:** Density of liquid diborane.

| Temperature |       | Density           |
|-------------|-------|-------------------|
| K           | °C    | g/cm <sup>3</sup> |
| 235.4       | −37.7 | 0.341             |
| 240.3       | −32.8 | 0.334             |
| 246.1       | −27.0 | 0.325             |
| 251.2       | −21.9 | 0.316             |
| 255.3       | −17.8 | 0.309             |
| 260.8       | −12.3 | 0.294             |
| 265.8       | −7.3  | 0.284             |
| 270.7       | −2.4  | 0.274             |
| 278.9       | +5.7  | 0.256             |
| 285.2       | +12.1 | 0.228             |
| 288.2       | +15.1 | 0.210             |

Data source: [52]

The density of liquid diborane as a function of temperature can be calculated from the equation:

$$\rho = 0.3140 - 0.001296t$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $t$  is the temperature in  $^{\circ}\text{C}$  [62].

Density data from several sources for temperatures ranging from 144 to 285 K were combined and curve fitted to give the following equation:

$$\rho = 0.4857 + 7.618 \times 10^{-4} T - 5.747 \times 10^{-6} T^2$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin [30] (Figure 2). It was more difficult to obtain data for saturated liquid density at above normal boiling point temperatures from 181 to 285 K. The curve-fitted function was afflicted with an inaccuracy of at least 3%:

$$\log \rho = 10.6409 - \frac{6528.72}{T} + 1.19681 \times \frac{10^6}{T^2} - 8.18767 \times \frac{10^7}{T^3}$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin.

**Figure 2:** Density of liquid diborane. (Reproduced and modified from [30].)

### 2.2.5 Compressibility and Velocity of Sound of Diborane

Values of the molar volume, heat capacity ratio, adiabatic compressibility, sound velocity, molar compressibility, pseudo-Grüneisen parameter, Poisson's ratio, and the Debye temperature of liquid diborane were tabulated for a temperature range 108–180 K [63].

The compressibility of liquid diborane was measured for pressures up to 7.3 MPa (1060 psia) and temperatures up to 287 K [52]. The results are graphed in Figure 3.

**Figure 3:** Diborane liquid compressibility isotherms. (Reprinted and adapted from [52], with permission from ©1950 American Chemical Society; permission conveyed through RightsLink.)

### 2.2.6 Viscosity of Diborane

The viscosity of liquid diborane is illustrated in Figure 4 in comparison with that of pentaborane and aluminum boranate. The viscosity of liquid diborane, the same data as shown in Figure 4, as a function of temperature can be expressed by the equation:

$$\eta = 36.86 \times 10^{-5} \rho^{\frac{1}{3}} e^{\left(\frac{551.8}{\rho T}\right)}$$

where  $\eta$  is the viscosity in Poise,  $\rho$  is the density in g/cm<sup>3</sup>, and  $T$  is the temperature in kelvin.

**Figure 4:** Viscosity of liquid diborane, pentaborane, and aluminum boranate. (Reprinted and adapted from [52], with permission from ©1950 American Chemical Society; permission conveyed through RightsLink.)

A different set of data within the temperature range 145–204 K was curve-fitted and resulted in the equation:

$$\log \eta = -2.027 + \frac{206.7}{T}$$

where  $\eta$  is the absolute viscosity in cPs and  $T$  is the temperature in kelvin. The data from this equation are illustrated in Figure 5.

**Figure 5:** Viscosity of liquid diborane. (Reproduced and modified from [30].)

### 2.2.7 Surface Tension of Diborane

At 203.4 K (−69.7°C) the surface tension of diborane was 10.9 dyn/cm and at 151.5 K (−121.6°C) the surface tension was measured as 18.6 dyn/cm. Surface tension data for diborane can be fitted to a linear equation:

$$\sigma = (65.7 - 0.227T)\rho^{\frac{2}{3}}$$

where  $\sigma$  is the surface tension in dyn/cm,  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin. Figure 6 shows the surface tension of diborane in comparison to that of pentaborane and aluminum boranate.

Another set of data for the temperature range 143–203 K was curve fitted and resulted in the equation:

$$\sigma = 72.07 - 0.5152T + 1.055 \times 10^{-3}T^2$$

where  $\sigma$  is the surface tension in dyn/cm and  $T$  is the temperature in kelvin. The curve generated from this equation is illustrated in Figure 7. See also [62].

**Figure 6:** Surface tension of diborane, pentaborane, and aluminum borane. (Reprinted and adapted from [52], with permission from ©1950 American Chemical Society; permission conveyed through RightsLink.)

**Figure 7:** Surface tension of saturated liquid diborane. (Reproduced and modified from [30].)

### 2.2.8 Thermal Conductivity and Heat Transfer Coefficient of Diborane

Diborane is not sufficiently thermally stable to serve as the cooling fluid in regeneratively cooled rocket engines. No thermal conductivity or heat transfer data were available. Attempts to use liquid diborane as a regenerative engine coolant were not successful and subsequent engine designs had to use both the fuel **and** the oxidizer for regenerative cooling of the thrust chamber and the nozzle. On the fuel side, the diborane decomposed under the coolant channel temperature conditions and solid residues coated the cooling channels and blocked heat transfer. On the oxidizer side, the OF<sub>2</sub> line burned out.

In an experimental program, heated-block heat transfer tests were conducted with both liquid and gaseous B<sub>2</sub>H<sub>6</sub> under conditions similar to those in a pressure-fed regeneratively cooled engine [64, 65]. Mass velocities were run in the range of 0.5 to 3.0 lb in<sup>-1</sup> s<sup>-1</sup> with coolant inlet pressures from 0.34 to 2.76 MPa (50 to 400 psia). A total test duration of 750 s was accumulated, with wall temperatures ranging from 294 to 589 K (70 to 600 °F). The results as Stanton Number and Nusselt Number correlations under bulk (B) conditions could be correlated by the relation:

$$N_{\text{NuB}} = 0.023 N_{\text{ReB}}^{0.8} N_{\text{PrB}}^{0.4}$$

where

$N_{\text{NuB}}$  = Nusselt Number =  $hD/T$

$N_{\text{ReB}}$  = Reynolds Number =  $DV\rho/\mu$

$N_{\text{PrB}}$  = Prandtl Number =  $C_p\mu/k$

$h$  = heat transfer coefficient

$D$  = characteristic length

$k$  = thermal conductivity

$V$  = velocity

$\rho$  = density

$C_p$  = heat capacity at constant pressure

$\mu$  = viscosity

### 2.2.9 Critical Constants of Diborane

The critical temperature and critical pressure of diborane were derived from PVT data [54]. The average critical temperature was  $289.8 \pm 0.2$  K ( $16.7 \pm 0.2$  °C). The average critical pressure was  $4.0 \pm 0.034$  MPa ( $581 \pm 5$  psia).

### 2.2.10 Solubility, Miscibility, Mixtures with Diborane:

#### Miscibility with Other Solvents

Diborane dissolves in hydrocarbons, e.g., *n*-hexane, at room temperature at 258 kPa (2.55 atm) pressure with a solubility of 4.2 g B<sub>2</sub>H<sub>6</sub>/100 g *n*-hexane. Similarly, its solubility in 1,4-dioxane at 293 K (20 °C) and 241 kPa (2.38 atm) is ~3.4 g B<sub>2</sub>H<sub>6</sub>/100 g dioxane. However, dioxane may react with diborane or pentaborane, forming ether adducts.

When examining the solubility of pressurant gases between 144 and 228 K, it was surprising to see that the solubility of helium in liquid diborane increased with increasing temperature, whereas the solubility of nitrogen decreased with increasing temperature [30]. The solubility of hydrogen in liquid diborane increased with increasing temperature [66].

### 2.2.11 Molecular Structure, Dipole Moment, and Molecular Orbital Calculations of Diborane

Because boron hydrides have more valence orbitals than valence electrons, they have been called electron-deficient molecules. This electron deficiency gives boranes enhanced reactivity (compared with hydrocarbons) and unique molecular structures. The electrons that form the bonds that hold the diborane molecule together occupy the  $1s$  orbital of hydrogen and four  $2sp^3$  orbitals of boron. Diborane has four terminal and two bridging hydrogen atoms. Each of the boron atoms forms two covalent B—H bonds, both the boron atoms and four terminal hydrogen atoms are located in the same plane. The two remaining hydrogen atoms are situated at equal distances from this plane on a line perpendicular to it and bisecting the B—B line (Figure 8).

**Figure 8:** Hydrogen bridges in the diborane molecule.

Each of these two bridge hydrogen atoms is joined to both boron atoms by three-center bonds. Each  $B \cdots H \cdots B$  bridge is regarded as a filled three-center localized bonding orbital, which utilizes one hydrogen orbital and one hybrid orbital from each of the boron atoms. The hydrogen atom contributes one electron to this orbital, and each boron atom contributes half an electron. The length of a terminal B—H bond in diborane is  $1.19 \text{ \AA}$ , that of a bridge  $B \cdots H$  bond is  $1.33 \text{ \AA}$ , the distance between the boron atoms is  $1.77 \text{ \AA}$ , and the H—B—H angle is  $121.5^\circ$ . The frequencies of the stretching vibrations of the terminal B—H bonds lie in the range  $2500\text{--}2600 \text{ cm}^{-1}$  in the infrared (IR) and Raman spectra, whereas the vibrational frequencies of the  $B \cdots H$  bridge bonds are situated at  $\sim 1600 \text{ cm}^{-1}$  and  $\sim 1800\text{--}2000 \text{ cm}^{-1}$  in the IR absorption spectra, and  $\sim 2100 \text{ cm}^{-1}$  in the Raman spectra. The energy of dissociation of diborane into two borane  $BH_3$  molecules is  $119.2 \text{ kJ/mol}$  ( $28.5 \text{ kcal/mol}$ ).

Diborane possesses a  $D_{2h}$  structure containing four terminal and two bridging hydrogen atoms. The structure of this molecule can be modeled using molecular orbital theory. The model determined by molecular orbital theory indicated that the bonds

between boron and the terminal hydrogen atoms are conventional two-center, two-electron covalent bonds. The bonding between the boron atoms and the bridging hydrogen atoms is, however, quite different from that in molecules such as hydrocarbons. Having used two electrons in bonding to the terminal hydrogen atoms, each boron has only one valence electron remaining for additional bonding. The bridging hydrogen atoms each provide one electron each. Thus, the  $\text{BH}_2\text{B}$  ring is held together with four electrons, an example of three-center–two-electron bonding. This type of bond is sometimes called a “*banana bond*.” The lengths of the  $\text{B}\cdots\text{H}$  bridge bonds and the  $\text{B}-\text{H}$  terminal bonds are 1.33 and 1.19 Å, respectively, and the difference in the lengths of these bonds reflects the difference in their strengths, the  $\text{B}\cdots\text{H}$  bridge bonds being relatively weaker than the  $\text{B}-\text{H}$  covalent bonds. Diborane is one of many compounds with such unusual hydrogen bridging bonding. The higher boranes are held together by similar bonds.

The molecular structures of diborane and hydrazine are significantly different, yet similar methods can be used for calculating their significant structures in the liquid state and predicted heat of evaporation [67].

At very high pressures, several molecules of borane aggregate into new structures held together by hydrogen bonds. Molecular and crystalline structures of  $(\text{BH}_3)_n$  have been theoretically studied in the pressure regime from 101 kPa to 100 GPa [68]. At lower pressures, crystals of the familiar molecular dimer are the structure of choice. There are a number of metastable structures for oligomers of  $\text{BH}_3$ , including cyclic trimers, tetramers, and hexamers. Higher oligomers are stabilized, for reasons of molecular compactness, by application of external pressure. Based on density functional theory (DFT) calculations, near 4 GPa a molecular crystal constructed from discrete trimers was predicted to replace the  $\beta$  diborane structure as the most stable phase and remain as such until 36 GPa.

High-pressure ground-state phases of crystalline diborane and their stability against decomposition into B and H were investigated by DFT calculations. Although  $\text{B}_2\text{H}_6$  is thermodynamically unstable to phase separation into B and H in the intermediate pressure range, it is restabilized beyond 350 GPa by forming metallic (conductive) structures with quite high density of states at the Fermi energy [69].

## 2.2.12 Absorption and Fluorescence Spectra of Diborane

### 2.2.12.1 Infrared Absorption Spectra of Diborane

The IR spectra of diborane are important for deriving thermodynamic properties and thermodynamic properties are important for calculating theoretical specific impulse of rocket engines with diborane. IR spectra of diborane are important for assuring the purity of the product and for identifying unwanted contaminants. The IR absorption spectrum of diborane was examined with high-resolution spectrometers from 3.7 to 30  $\mu\text{m}$  [70]. The rotational fine structure in two bands of each of the three types characteristic of asymmetric top molecules could be resolved. All results and observations were consistent with the conclusion that diborane has a bridge structure, and belongs

to the same symmetry point group,  $V_h$ , as ethylene. The observation and structure of the band with center at  $368.7\text{ cm}^{-1}$  provided spectroscopic evidence that the molecule is non-planar, and made the assignment of fundamental frequencies more definite. Data on all bands fit quite well the symmetric top approximation and predicted rotational constants. For the type A bands nearly every line obtained was accounted for, except those in or near the central maxima.

Another IR spectrum of liquid diborane was recorded within the range  $4500\text{--}10500\text{ cm}^{-1}$  and a complete assignment for the observed overtone and combination bands was possible [71]. The IR spectrum of  $\text{B}_2\text{H}_6$  gas at 50 mm Hg pressure is shown in Figure 9.

**Figure 9:** Infrared spectrum of diborane gas. (Reproduced and modified with permission from [72])

The IR spectrum of diborane showed only bands of lesser intensity indicating the absence of a first overtone and some uncertainty as to the presence of a second overtone [73]. Assuming  $D_{2h}$  point group symmetry, the bands observed have been assigned. The spectrum of diborane in the overtone region showed six weak bands between  $4800$  and  $5800\text{ cm}^{-1}$ . The gas was studied under greater pressure, longer path length and higher resolving power giving a spectrum in which the differences in intensity of the bands observed could be used as a guide in making assignments. By examining diborane under two atmospheres of pressure in a 40-cm cell, it was possible to observe the band at  $7580\text{ cm}^{-1}$ , which had not previously been reported.

The rotational structure of the bands in high-resolution IR spectra of  $\text{B}_2\text{H}_6$  vapor was analyzed for Coriolis perturbations owing to rotation about the axis of least moment of inertia (the B—B axis) [74]. Interactions between the Type A fundamental and inactive fundamentals confirmed the assignment of  $\nu_5$  at  $833\text{ cm}^{-1}$ . The assignment of unobserved fundamental vibrations of diborane was more difficult.

Polarized IR spectra of single crystals of diborane compared with spectra of the vapor and liquid showed evidence for the existence of three solid phases and the struc-

ture of a low-temperature form was partially elucidated [75]. This phase was found to be monoclinic with two or more molecules per primitive unit cell located on sites of symmetry no higher than  $C_i$ .

The two IR-active terminal B—H stretching bands,  $\nu_8$  and  $\nu_{16}$ , of  $^{10}\text{B}_2\text{H}_6$  and  $^{11}\text{B}_2\text{H}_6$  were studied with a resolution of  $0.04\text{--}0.05\text{ cm}^{-1}$ , and several ground-state rotational constants and moments of inertia were obtained [76]. These constants were then used to derive the following structural parameters:  $\text{B}\cdots\text{B} = 1.7628 \pm 0.0026\text{ \AA}$ ,  $\text{B—H}_{\text{terminal}} = 1.2005 \pm 0.0036\text{ \AA}$ ,  $\text{B}\cdots\text{H}_{\text{bridge}} = 1.3204 \pm 0.0010\text{ \AA}$ ,  $\angle\text{H}_{\text{terminal}}\text{BH}_{\text{terminal}} = 121.0 \pm 0.6^\circ$ , and  $\angle\text{H}_{\text{bridge}}\text{BH}_{\text{bridge}} = 96.2 \pm 0.2^\circ$ .

A thorough investigation of the IR spectra of diborane in the gas phase and polycrystalline films of normal and  $^{10}\text{B}$ -enriched samples of  $\text{B}_2\text{H}_6$  and  $\text{B}_2\text{D}_6$ , in conjunction with those from previous Raman studies, enabled a complete and unambiguous assignment of all 18 fundamental vibrations of  $\text{B}_2\text{H}_6$  and  $\text{B}_2\text{D}_6$  [77]. All previously uncertain or unassigned fundamentals were located by direct observation in the crystal phase and by means of one or more IR or Raman active combination bands. Boron isotopic vibration frequency shifts were used to analyze a number of Fermi resonances.

Four infrared active bands of  $^{10}\text{B}_2\text{H}_6$  were studied with a resolution of  $0.05\text{ cm}^{-1}$  [78]. From assignments in these bands, asymmetric-rotor ground-state parameters were determined from more than 500 possible combination differences. Upper-state parameters for all four vibrations were determined, and a few local perturbations were noted.

A total of 114 spectroscopic data accumulated from six isotopic species of diborane were used to determine the empirical harmonic potential functions [79]. Of the 33 independent force constants, 30 could be determined and agreed with scaled *ab initio* force constants. The potential function reproduced all known frequency, isotopic frequency shift, Coriolis, and centrifugal distortion with good accuracy.

An analysis of IR absorption bands near  $800\text{ cm}^{-1}$  of two isotopic species,  $^{10}\text{B}_2\text{H}_6$  and  $^{11}\text{B}_2\text{H}_6$ , of diborane has been carried out using IR spectra recorded with a resolution of approximately  $0.003\text{ cm}^{-1}$  [80]. It was possible to derive precise energy levels and Hamiltonian constants for the 41 vibrational states of both isotopic species.

As the simplest stable boron hydride in its condensed phase, diborane exhibits an interesting structural chemistry with uniquely bridging hydrogen bonds. Room-temperature IR absorption spectra of solid diborane compressed to pressures as high as 50 GPa using a diamond anvil cell displayed rich, sharply resolved fundamentals and overtones of the IR active bands, consistent with previous low-temperature IR measurements of condensed diborane at ambient pressure [81]. When compressed stepwise to 50 GPa, several structural transformations could be identified at pressures of 3.5, 6.9, and 14.7 GPa, as indicated by the changes in the band profile as well as the pressure dependence of the characteristic IR modes and bandwidths. These transformations can be interpreted as being enhanced intermolecular interactions resulting from compression. The geometry of the four-membered ring of  $\text{B}_2\text{H}_6\text{B}_2\text{H}_6$  did not seem

to be altered significantly during the transformations, and the  $\text{B}_2\text{H}_6\text{B}_2\text{H}_6$  molecule remained chemically stable up to 50 GPa.

Interpretation of some of the early period IR spectra was still based on the erroneous assumption that the molecule resembled that of ethane and that there was a potential barrier to internal rotation within the molecule (actually, the two halves do not rotate around the axis connecting the boron atoms) [82, 83]. Later IR spectra within the range 1–25  $\mu\text{m}$  ruled out the ethane-type structure but agreed very well with the interpretation of the electron diffraction results in terms of a bridge model [84].

Deuterated diborane was prepared by isotopic exchange and its IR absorption spectrum lent support to the assignment based on a hydrogen bridge model [85]. Redetermination of the Raman spectrum of normal diborane indicated several changes from previous assignments. The resulting vibrational assignment was used to calculate the thermodynamic properties of diborane within the range 100–1500 K.

#### 2.2.12.2 Raman Fluorescence Spectra of Diborane

High-resolution Raman spectra of the  $\nu_4$  bands of  $^{11}\text{B}_2\text{H}_6$  and  $^{11}\text{B}^{10}\text{BH}_6$  have been recorded using a high-resolution spectrometer based on the inverse Raman effect [86]. Q-branches have been observed, but P- and R-branches were too weak to be seen. A weak Coriolis resonance with the  $2\nu_{10}$  level was present in the  $^{11}\text{B}_2\text{H}_6$  spectrum. The band centers obtained were at 790.9829 and 804.76985  $\text{cm}^{-1}$  for  $^{11}\text{B}_2\text{H}_6$  and  $^{10}\text{B}^{11}\text{BH}_6$  respectively.

As an electron-deficient molecule with unique hydrogen bridge bonding, diborane has created considerable interest in structural chemistry. Pressure-induced structural transformations of diborane at pressures around 4 GPa, where diborane underwent a liquid-solid phase transformation to a new high-pressure phase I with a possible structure similar to the low-temperature phase, were probed by *in situ* Raman spectroscopy [87]. When compressed to above 6 GPa, the spectral features, such as doubling of the lattice modes, appearance of several new internal modes and emergence of a new ring stretch mode, indicated the structural transformation to another new high-pressure phase II. This phase had a possible extended network structure of higher hydrides of borane. At pressures above 14 GPa, diborane transformed to yet another high-pressure phase III. All of the observed pressure-induced structural transformations were completely reversible upon decompression.

#### 2.2.13 Dielectric Constant of Diborane

Diborane is a non-polar liquid (as opposed to  $\text{H}_2\text{O}$ ), and the dielectric constant of the liquid can be represented by the equation [60]:

$$\epsilon = 2.3721 - 0.002765 T$$

where  $\epsilon$  is the dielectric constant (dimensionless) and  $T$  is the temperature in kelvin.

### 2.2.14 Thermodynamic Properties and Thermal Properties of Diborane

There are four different types of bonds that hold the boranes together:

|           |                                                 |  | Bond energy |         |
|-----------|-------------------------------------------------|--|-------------|---------|
|           |                                                 |  | kcal/bond   | kJ/bond |
| B—H       | electron pair, two-center                       |  | 93.1        | 389.5   |
| B—B       | electron pair, two-center                       |  | 83.1        | 347.7   |
| B···H···B | one electron pair for two ligands, three-center |  | 107.2       | 448.5   |
| B···B···B | one electron pair for two ligands, three-center |  | 97.7        | 408.8   |

If one assumes that these bonds act independently of each other, the enthalpy of formation of boranes can be calculated assuming additive behavior [88, 89].

#### 2.2.14.1 Heat Capacity of Diborane

The heat capacity of gaseous diborane as a function of temperature can be calculated from the Shomate Equation:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2},$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$ , A, B, C, D, and E are constants, and  $\tau$  is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 4. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor (see Section 2.2.14.3). These equations were curve-fitted from data covering ranges from 298 to 1200 K and from 1200 to 6000 K, giving two overlapping sets of data. Of course, at those high temperatures diborane would long since have decomposed into the elements.

**Table 4:** Constants for vapor phase thermodynamic properties of diborane.

| Temperature range, K | 298–1200  | 1200–6000 |
|----------------------|-----------|-----------|
| A                    | −12.42167 | 161.6275  |
| B                    | 267.6112  | 11.23329  |
| C                    | −152.2612 | −2.178187 |
| D                    | 33.15879  | 0.146029  |
| E                    | 0.300489  | −36.76757 |
| F                    | 35.09886  | −89.40873 |
| G                    | 146.5115  | 320.5023  |
| H                    | 41.00303  | 41.00303  |

Data source: [53]

The heat capacity of solid diborane from 14 to 108 K was measured [58]. For temperatures below 21 K, the heat capacity followed the equation:

$$C_v = 1.486 \times 10^{-4} T^3 \text{ cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}.$$

At 89.54 K the heat capacity of solid diborane was  $48.9 \text{ kJ mol}^{-1} \text{ K}^{-1}$  ( $11.688 \text{ cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}$ ). The heat capacity of liquid diborane was measured between 114 and 176 K. The average heat capacity was close to  $75 \text{ kJ mol}^{-1} \text{ K}^{-1}$  ( $18 \text{ cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}$ ). The heat capacity of saturated liquid diborane at temperatures above the normal boiling point increased sharply as it approached the critical temperature [59] (Figure 10).

**Figure 10:** Heat capacity of saturated liquid diborane. (Reprinted and adapted from [59], with permission from ©1953 American Chemical Society; permission conveyed through RightsLink.)

Attempts to perform a curve fit of two sets of heat capacity data (from [58] and [59]) for liquid diborane between 112 and 282 K encountered difficulties, although the match in the overlap in the adjoining regions was good (as shown in Figure 11).

Only after the four highest data points with the worst scatter were eliminated was a reasonably good fit to the data achieved by the equation:

$$c_p = 0.4266 + 4.358 \times 10^{-3} T - 2.353 \times 10^{-5} T^2 + 2.05 \times 10^{-10} T^4$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ K}^{-1}$  and  $T$  is the temperature in kelvin [30]. The heat capacity curve generated from this equation is illustrated in Figure 12. It does not go through a minimum at 140 K, but remains fairly constant within that range.

**Figure 12:** Heat capacity of saturated liquid diborane. (Reproduced and modified from [30].)

### 2.2.14.2 Enthalpy of Formation and Heat of Combustion of Diborane

Accurate data for the heat of combustion of boranes and alkylboranes are important for their evaluation as jet engine fuels and rocket propellants. The presence of condensed phase reaction products such as  $B_2O_3$  and  $B(OH)_3$  made calorimetric measurements very difficult. In some cases the data needed to be corrected for incomplete reaction.

### 2.2.14.3 Enthalpy of Formation of Diborane

The enthalpies of formation of diborane and pentaborane were determined by measurements of the heat of decomposition into amorphous boron and hydrogen in a calorimeter [90]. The enthalpies of formation at 298 K (25 °C) from amorphous boron and hydrogen were  $+28.1 \pm 2.2$  kJ/mol ( $+6.73 \pm 0.52$  kcal/mol) for diborane (gas) and  $54.4 \pm 1.6$  kJ/mol ( $+12.99 \pm 0.39$  kcal/mol) for pentaborane (gas). The heats of decomposition are exothermic and therefore negative numbers. The enthalpies of formation are the opposite.

The vapor phase excess enthalpy above the standard enthalpy of formation  $\Delta H^\circ_{f,298}$  of diborane can be calculated from the Shomate Equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where A, B, C, D, E, and F are constants, and  $\tau$  is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 4 above. The same coefficients (and others) were used for a formula expressing the heat capacity of the vapor (see Section 2.2.14.1). These equations were curve-fitted from data covering a range from 298 to 6000 K.

The heat of formation of liquid diborane at its normal boiling point is  $+21 \pm 16$  kJ/mol ( $+5 \pm 4$  kcal/mol =  $325 \pm 260$  BTU/lb). Other sources gave the heat of formation of liquid diborane at 298 K (under pressure) as  $+4.97 \pm 4.0$  kcal/mol. The density under those conditions would be  $0.4371$  g/cm<sup>3</sup>. See also [91] and [92].

### 2.2.14.4 Heat of Combustion of Diborane

The heat of combustion of diborane is difficult to determine because the gas ignited as soon as oxygen is admitted. The combustion may not be complete because some of the diborane decomposes and forms higher boranes before it has a chance to burn to completion. Reported heats of combustion for diborane gas vary.

The net (lower) heat of combustion of diborane alone is 2018 kJ/mol = 72924 kJ/kg = 31373 BTU/lb [93]. Other sources quote the heat of combustion of diborane as 2082 kJ/mol = 75258 kJ/kg = 32377 BTU/lb [15].

### 2.2.14.5 Heat of Fusion of Diborane

The heat of fusion of diborane at the normal melting point was 4.473 kJ/mol = 1.0691 kcal/mol (average of four runs) [58].

#### 2.2.14.6 Heat of Vaporization of Diborane

The heat of vaporization of diborane at the normal boiling point is 14.28 kJ/mol ( $3.413 \pm 0.0015$  kcal/mol) [57]. The heat of vaporization as a function of temperature can be expressed by the equation:

$$\Delta H_{\text{vap}} = 546.2(T_c - T)^{0.39} = 546.2(289.7 - T)^{0.39}$$

where  $\Delta H_{\text{vap}}$  is the heat of evaporation in cal/mol,  $T_c$  is the critical temperature (289.7 K) and  $T$  is the temperature in kelvin [94]. For instance, the heat of evaporation at 179.4 K from this equation is 3.42 kcal/mol. Other experimenters reported a heat of vaporization of  $14.276 \pm 0.012$  kJ/mol =  $3.412 \pm 0.003$  kcal/mol [58].

### 2.3 Chemical Properties of Diborane

#### 2.3.1 Literature on Borane Chemistry

There exist many summary publications and monographs on borane chemistry. Only a few can be listed here [32, 95–97]. A very comprehensive summary of the chemistry of diborane and diborane derivatives with 238 references is a good source of information on the versatile reactions with diborane, leading to many other useful products [98].

#### 2.3.2 Pyrolysis of Diborane

Diborane is unstable at room temperature. When heated, diborane will decompose with the formation of higher boron hydrides (mostly pentaborane  $B_5H_9$  and decaborane  $B_{10}H_{14}$ ) and an array of unstable intermediates [99, 100]. The first step in the decomposition of diborane would be its dissociation into two molecules of borine,  $BH_3$ , with which it is in equilibrium [101]. Splitting diborane into two borines would be an endothermic reaction and require 134 kJ/mol (32 kcal/mol) of diborane.

The kinetics of the pyrolysis of diborane between 358 and 436 K (85 and 163 °C) indicated a fractional order rate constant that appeared to be proportional to the square root of the initial pressure (indicating a free radical mechanism) times the 5/2 power of the fraction of unreacted diborane, and was depressed by the addition of dihydrogen but unaffected by an equivalent amount of dinitrogen or by an increase in surface [102]. The reaction is believed to be a radical-type polymerization process complicated by quasi-reversible dehydrogenation.

The rate of pyrolysis and the product ratio of desired higher boranes can be influenced by the choice of proper heterogeneous catalysts [103]. It was hoped that some catalyst might be found that would promote the selective formation of pentaborane(9) from diborane and avoid the formation of “yellow solids” [104].

At very high temperatures the only products are polymeric, non-volatile boron hydrides with very low hydrogen content. The pyrolysis of mixtures of diborane with other boron hydrides leads to the same undesirable results [105].

Pyrolysis of diborane was carried out in a borosilicate glass cell designed to freeze out products that would condense at 194.6 K (−78.5 °C) [106]. Between 373 and 403 K (100° and 130 °C) pentaborane(11) was the main condensable product. The stoichiometry of such a reaction should cause a decrease in total pressure, as pentaborane(11) exhibits little vapor pressure at the condensation temperature:

However, without exception, an initial increase in pressure was observed. This pressure increase was not due to fast initial decomposition of pentaborane(11) to polymer or pentaborane(9), nor to slow attainment of temperature equilibrium in the reaction vessel. An alternative explanation appeared to be a high initial concentration of unstable intermediates in the formation of pentaborane(11). See also [107].

The composition of diborane decomposition products in a flow reactor was measured in real time by mass spectrometry as a function of temperature, dwell time, pressure, and surface : volume ratio [108]. One of the intermediates is borine  $\text{BH}_3$ . The decomposition of diborane at low pressures is dominated by surface effects [109].

The mechanisms by which gaseous boron hydrides so readily interconvert and build up into larger clusters are based on a complex series of interconversion reactions that are still not quite understood. Initial reaction rates have been studied mass spectrometrically to obtain rate equations, orders of reaction and energies of activation [110, 111]. Detailed and continuous product analysis for evolved  $\text{H}_2$  and all the volatile boranes formed, coupled with a study of co-thermolysis reactions of selected pairs of boranes gave further insight into the processes occurring. The thermolysis of  $\text{B}_2\text{H}_6$ ,  $\text{B}_4\text{H}_{10}$ ,  $\text{B}_5\text{H}_{11}$ , and  $\text{B}_6\text{H}_{10}$  and the effects of added  $\text{H}_2$  and the co-thermolysis of  $\text{B}_6\text{H}_{10}$  with alkenes was also examined. Ultraviolet (UV) absorption spectra and photolytic stability of eight volatile boranes and the reaction kinetics of  $\text{B}_6\text{H}_{10}$  photolysis were measured to support the kinetic studies.

Among the decomposition products of diborane, the less common boron hydrides  $\text{B}_3\text{H}_7$  and  $\text{B}_3\text{H}_9$  were observed as trace species over the mass range 34–38 amu [112]. Additional reactions lead to formation of tetraborane and pentaborane. Kinetic rates for a proposed five-step reaction leading to the desired pentaborane were tabulated, along with forward rate and reverse rate constants.

The rate constants for the association of two boranes to form diborane were investigated by computational chemistry using several different methods [113]. Two variations of a multi-step mechanism for diborane pyrolysis were presented: one was initiated by the step  $\text{B}_2\text{H}_6 \rightleftharpoons 2\text{BH}_3$  whereas the other began with  $2\text{B}_2\text{H}_6 \rightleftharpoons \text{B}_3\text{H}_9 + \text{BH}_3$  as the initial elementary step. Both reactions were 3/2 order in diborane and had the same activation energy (120 kJ/mol = 28.65 kcal/mol at 420 K). The rate-limiting step in the initial stage of diborane pyrolysis is the concerted formation and decomposition of  $\text{B}_3\text{H}_9$ . Another mechanism involved a  $\text{C}_2$ -symmetry penta-coordinate  $\text{B}_3\text{H}_9$  structure that, although an electronic minimum, was not a stationary point on the free energy path between  $\text{B}_2\text{H}_6 + \text{BH}_3 \rightarrow \text{B}_3\text{H}_7 + \text{H}_2$ .

### 2.3.3 Photolysis of Diborane

The photolysis of diborane has been studied as a potential method for obtaining higher boranes by a more selective method than thermal pyrolysis, which forms many useless byproducts [114]. The photolysis of diborane at 1849Å has been studied with UV light from a mercury vapor lamp [115]. The products were  $H_2$ ,  $B_4H_{10}$ ,  $B_5H_{11}$ , and, at low pressures, a  $-BH-$  polymer. A mechanism consistent with the kinetic data and suggested by the kinetic results of thermal and photosensitized decomposition of diborane was postulated. The  $B_5H_{11}$  was assumed to be formed from a dissociation of  $B_2H_6$  into  $2BH_3$ , the latter arising from an excited molecule. The  $B_4H_{10}$  and polymer were assumed to be formed from a dissociation of  $B_2H_6$  into  $\cdot B_2H_5$  and  $H\cdot$ , followed by radical recombination. The primary quantum yield of the step forming  $\cdot B_2H_5$  and  $H\cdot$  was about 10 times higher than that of the one forming  $2BH_3$ . Borane  $BH_3$  is an intermediate in the UV-facilitated deuterium-hydrogen exchange in diborane [116].

### 2.3.4 Reactions with Diborane

Diborane is a mildly endothermic compound that is only on the verge of stability at room temperature, as it slowly decomposes during prolonged storage. Pure diborane does not ignite spontaneously in dry air, but in pure oxygen it will autoignite immediately. Once ignited in air or oxygen, it burns with a bright green flame. In moist air it will hydrolyze and form boric acid fumes. It has a repugnant odor and can be detected by this if a leak should occur (see Toxicity of Diborane, Section 2.8).

Because of the high reactivity of diborane, the types of reactions that it can undergo are unusually numerous and varied, as summarized in a review paper on the reactions of diborane [117]. Reactions that would be of interest here are those with hypergolic oxidizers that lead to immediate ignition with short ignition delays.

#### 2.3.4.1 Diborane Reactions with Lewis Bases

Diborane is a highly reactive and versatile reagent that has a large number of applications. Its dominating reaction pattern is the formation of Lewis adducts with Lewis bases. The complexes with tetrahydrofuran (THF) and dimethyl sulfide are notable; both are liquid compounds that are popular reducing agents in organic chemistry and they are more easy to handle than diborane itself. In these 1:1 complexes, boron atom assumes a tetrahedral geometry, being bound to three hydride hydrogens and the Lewis base (THF or  $Me_2S$ ). The THF adduct is usually prepared as a 1:5 solution in THF. The latter is indefinitely stable when stored under nitrogen at room temperature. Diborane reacts with ammonia to form ammonia borane or the diammoniate of diborane (DADB), depending on the conditions used.

The reactions between diborane and Lewis bases are exothermic, like many other acid-base salt-forming reactions [118]. Part of the released energy goes into splitting diborane into two borine entities that then react with the amine that has a free electron pair. Depending on the affinity between borane and different amines, the amine com-

ponent of the adducts can be exchanged, forming new adducts. Section 7.4 contains detailed information on diborane-amine Lewis adducts.

The dissociation of diborane and the formation of adducts with trimethylamine or carbon monoxide imply the transitory existence of borine,  $\text{BH}_3$  [119].  $\text{H}_3\text{BCO}$  exists only in an equilibrium mixture with  $\text{B}_2\text{H}_6$  and  $\text{CO}$  in the presence of a large excess of  $\text{CO}$ . The carbon monoxide in  $\text{H}_3\text{BCO}$  is readily replaced by trimethylamine, which has a higher affinity to  $\text{BH}_3$  than  $\text{CO}$ .

#### 2.3.4.2 Diborane Reactions with Alkenes and Alkynes

The addition of diborane in ether to alkenes is very rapid and almost quantitative. The addition of diborane to unsaturated compounds, is carried out by passing a current of diborane into an ether or THF solution of the alkene, the resulting trialkylborane being separated by distillation. The diborane-THF adduct is a useful organic synthesis reagent for *hydroboration*. *Hydroboration* is a widely used reaction where alkenes add across the B—H bonds to give trialkylboranes [120, 121]:

The reaction of diborane (diluted with hydrogen) and acetylene in a flow reactor gave a mixture of unidentified liquid alkylboranes [122]. The reaction of a diborane solution in THF with acetylene was exothermic and resulted in a white solid precipitate that was pyrophoric in air [123].

It was assumed that the reaction in the presence of an excess of acetylene would proceed as

The heat of combustion of the reaction product of diborane with acetylene, a yellow, viscous liquid with a gross formula of  $\text{B}_2\text{C}_4\text{H}_{10}$  and a molecular mass of 79.75 g/mol was 49511 kJ/kg = 3948 kJ/mol = 21300 BTU/lb [124].

Reactions of diborane with alkanes instead of alkenes take place only at higher temperatures and result in a medley of products of only limited commercial value [125].

#### 2.3.4.3 Diborane Reactions with Carboxylic Acids

Diborane can be used as a reducing agent comparable with the reactivity of lithium aluminum hydride. Diborane readily reduces carboxylic acids to the corresponding alcohols, whereas ketones react only sluggishly.

#### 2.3.4.4 Hydrolysis of Diborane

Diborane hydrolyzes with water to form hydrogen and boric acid [126]. This reaction with ubiquitous moisture in air can have very undesirable consequences.

The heat of reaction of gaseous diborane with water to form gaseous hydrogen and a solution of boric acid has been measured by passing gaseous diborane through

two successive bubblers in a calorimeter [127]. The heat of reaction was  $-466.34 \pm 2.26$  kJ/mol ( $-111.46 \pm 0.54$  kcal/mol).

#### 2.3.4.5 Exothermic Reactions of Diborane

The reaction of diborane with hydrazine is strongly exothermic and results in spontaneous ignition, which would make it suitable as a hypergolic bipropellant reaction. The reaction is:

The molecular weight of the exhaust is very low, as it is mostly hydrogen gas with solid BN as a condensed phase. This allows a high specific impulse in a rocket. This combination can be used as a hypergolic rocket propellant. A similar reaction takes place between pentaborane and hydrazine.

These Lewis acid-Lewis base reactions are strongly exothermic and in the case of hydrazine can result in spontaneous ignition and a new type of bipropellant rocket propellant combination that does not involve traditional oxidizers [128].

#### 2.3.4.6 Reactions of Diborane with Oxygen

Diborane autoignites spontaneously in oxygen and occasionally in air. The kinetics of oxygen/diborane reactions will be discussed in a future volume on hypergolic propellants along with flame speeds and critical diameters.

### 2.3.5 Analysis of Diborane

#### 2.3.5.1 Assay of Diborane

The analysis of diborane in mixtures with other boranes and purity control of pure diborane can be done by gas chromatography [129, 130] or mass spectrometry [131]. For gas-liquid chromatography, Celite coated with paraffin oil or tricresyl phosphate was used as the stationary phase. Small amounts of ethane, which was present in diborane as an impurity, could be separated from diborane using this method.

Mixtures of boranes can be analyzed using IR spectroscopic methods. A method was developed for the determination of the four constituents, diborane, tetraborane, and dihydropentaborane in a relatively larger amount of pentaborane [132].

#### 2.3.5.2 Gas Detectors and Warning Monitors

Although diborane can be detected by its unpleasant odor at very low concentrations ( $2$  to  $4$  mg/m<sup>3</sup>), it is recommended to equip borane storage areas with recording gas detectors and monitors, which can trigger an audible alarm if the concentration exceeds a safe level. Gas detectors described in the literature respond to diborane as well as the higher boranes. A continuous, automatic coulometric titration system capable of determining diborane and decaborane in concentrations down to  $0.2$  ppm by volume was developed to monitor boranes in air. In this system, boranes scrubbed out of

air into a sodium bicarbonate/potassium iodide electrolyte were titrated with coulometrically generated iodine [133]. Spot tests may not be accurate enough to provide meaningful answers [134].

Instruments for monitoring atmospheres contaminated with boron hydrides used the non-specific reduction of triphenyl tetrazolium chloride by boron hydrides to form the red-colored formazan [135]. Metered air samples were drawn through filter paper or cloth tape impregnated with the reagent solution. The red color produced was measured by a differential reflectance photometer. The instruments were calibrated with diborane, pentaborane, and decaborane. The field model could detect 0.1 ppm of decaborane and 1.5 ppm of pentaborane, whereas the stationary, automatic instrument was capable of detecting 0.1 ppm of either compound.

## 2.4 Handling of Diborane

Equipment for the handling of diborane can be made from most common materials of construction, preferably stainless steel. The equipment has to be designed such that it can be evacuated and filled with inert gas before borane is admitted into the system. In particular, one must avoid intrusion of air into a system filled with diborane at sub-atmospheric pressure. Intrusion of air may cause explosions. It is therefore best practice to maintain a positive pressure at all times in diborane systems to prevent accidental intrusion of air.

Diborane is supplied as compressed gas in steel cylinders. However, it is recommended to store diborane at temperatures below 273 K (0 °C) to prevent decomposition. Remember that diborane has a positive enthalpy of formation, releasing energy when it decomposes. The rate of decomposition depends on the type of materials it is in contact with.

## 2.5 Materials of Construction for Diborane

The most comprehensive summary of recommended and compatible materials of construction for systems in contact with diborane is in the Diborane Handbook [30].

Radioactive tracer test methods that were successfully used to study metal corrosion in  $N_2H_4$  can possibly also be used for  $B_2H_6$  [136–138]. Materials compatibility tests with diborane were included in a series of tests that also tested hydrazine and oxygen difluoride. Metal bomblets of high pressure capability were fabricated from Ti-6Al-4V, Al-6061-T6, and CRES-304. Diborane was stored at 128 K (–230 °F) over a period of 3 months in these vessels. The measurement of minute amounts of hydrogen indicated that very little interaction between diborane and the metal containers was taking place. For instance, in the order of increasing hydrogen build-up over diborane were the metals 304 steel < 6061 aluminum < 6Al-4V titanium. Looking for leached

metals, no measurable quantity (less than 0.02 ppm) of titanium was taken up from a 6Al-4V titanium vessel by liquid diborane at 128 K (–230 °F), although a trace of aluminum was found.

Flow decay studies performed by TRW Systems Group examined clogging materials not only in diborane, but also in hydrazine, oxygen difluoride, and dinitrogen tetroxide, all in the category of space-storable propellants [139–141]. Approximately 100 flow tests were conducted flowing liquid diborane through two different size orifices. One was a 0.25 mm (0.010 in.) diameter and the other was a 0.51 mm (0.020-in.) diameter orifice, followed by a 2- $\mu$ m nominal to 10- $\mu$ m absolute rated filter and a 10- $\mu$ m absolute rated surface tension acquisition screen [142]. The diborane propellant used was both neat and doped and flowed under both isothermal and changing temperature (chilling) conditions. The dopants used were oxides of stainless steel, oxides of aluminum, low molecular weight hydrocarbons and finely divided Teflon. Temperature was varied from 222 to 122 K (–60 to –240 °F) for several experiments. No evidence for flow decay or blockage of any test section was found.

## 2.6 Fire-Fighting Equipment

Gaseous diborane that has leaked from a system and ignited accidentally cannot be extinguished with carbon dioxide fire extinguishers. It has been shown that diborane continues to burn in mixtures with carbon dioxide and air [143]. Tetrachloromethane, which was once used for fire extinguishers in electric installations, reacted vigorously with burning diborane under formation of soot and hydrogen chloride. If sand is poured on a diborane fire, the gas continues to burn on the top of the sand pile where it comes into contact with air. Bicarbonate powder, which is often used in dry chemical fire extinguishers, has a similar effect, i.e., it is ineffective against diborane fires. Somewhere it was recommended to fight gaseous diborane fires with water spray, but that was a bad choice. However, the hydrolysis of diborane is exothermic and develops hydrogen gas. If hydrogen gas mixes with air and reignites, it may explode, in particular in confined spaces. Burning liquid diborane should not be extinguished with water. A large amount of carbon dioxide snow may cool the puddle of burning liquid diborane to the point where the vapor pressure is lowered below the flammable limit in air.

## 2.7 Safety Properties of Diborane

Laboratories where diborane is handled must have adequate ventilation and work stations with well-drawing fume hoods. Diborane is both a toxicity and an explosion hazard [144]. A Hazard Ranking Score (HRS) was developed for hazardous chemicals, a composite index based on autoignition temperature, flammable range in air, the Na-

tional Fire Protection Association (NFPA) parameter, ionization potential parameter (for ease of detection), and trinitrotoluene (TNT) equivalency [145]. Chemicals were ranked on a scale from 0 (safe) to 100 (extremely hazardous). The NFPA diamond summarizes the hazard of chemicals through four characteristics: Health, Flammability, Instability or Reactivity, and Special Hazard. On a scale from 0 to 100, diborane received a HRS of 76.8, one of the highest of all chemicals evaluated. For comparison, pentaborane received an HRS of 64.4, and unsymmetrical dimethylhydrazine was ranked at 42.9. Triethylaluminum was ranked at 57.8. Safety procedures for the handling of diborane and the other boranes and alkylboranes have been established to prevent damage to personnel and facilities [146].

## 2.8 Toxicity of Diborane

All boranes are highly toxic and inhalation of borane vapors must be avoided. The toxic properties of all boron hydrides have been extensively investigated, in particular during the period in the past century when borane derivatives were actively proposed and evaluated as high-energy fuels for jet engines [147]. In the end, it was the toxicity of these compounds that prevented a more widespread application in military aviation. The mode of toxic action of diborane within the human body remained unknown for a long time. Primary effects of exposure involved the central nervous system. Prolonged exposure may also cause damage to both the liver and the kidneys. Skin contact with this compound caused severe chemical burns. The effects of ingestion are unknown. The most frequent cause of personnel exposure to boranes was accidental or negligent inhalation.

Within the human body the primary effect of exposure to diborane is pulmonary irritation. Prolonged exposure to diborane may also cause damage to both the kidney and the liver. Animal experimentation revealed that diborane compared with phosphene ranks below pentaborane and decaborane in its toxicological effects. A therapy of diborane poisoning must be aimed at the prevention of edema and assisting respiration until the lung tissue has healed. Additional animal studies revealed pulmonary edema (presence of serous fluid in lung tissues) and hemorrhage, tracheal and lung congestion, and liver and kidney damage. See also [27, 148–151].

### 2.8.1 Inhalation Toxicity of Diborane as Determined by Animal Exposure Tests

Diborane hydrolyzes in the respiratory tract and forms boric acid, which attacks the trachea and lung tissue. Higher boranes do not hydrolyze as rapidly as diborane and can penetrate deeper into the body. Higher boranes are predominantly toxic to the central nervous system. The acute inhalation toxicity LC<sub>50</sub> of diborane in rats for a 4-h inhalation period is about 50 ppm [152]. The necropsy revealed pulmonary edema and hemorrhaging. Tests with lower concentrations where rats were exposed repeatedly

6 h/day, 5 days/week to  $6 \text{ mg B}_2\text{H}_6/\text{m}^3$  resulted in lung damage after only 2–3 weeks of testing.

The acute toxicity of diborane by inhalation to dogs, rats, and guinea pigs was determined by exposing groups of six rats to diborane concentrations of 52 to  $492 \text{ mg}/\text{m}^3$  (47 to 446 ppm) for 1–4 h (Ct 10400 to  $37200 \text{ mg min}/\text{m}^3$ ) [153]. Animals were observed for 14 days after exposure, mortality was recorded, and pathological examination of animals dying as a result of gassing was performed. At the two highest concentrations, 317 and  $492 \text{ mg}/\text{m}^3$ , all animals died within 2 h after removal from gassing chamber. For chronic exposure (6 h/day, 5 days/week), two dogs and 18 rats were exposed to a diborane concentration of  $6 \text{ mg}/\text{m}^3$  (5 ppm) for periods of 3 weeks to 6 months. Pathological examination of exposed animals was performed. In another test with a lower concentration, 2 dogs, 20 rats, and 10 guinea pigs were exposed to diborane concentrations of  $0.8\text{--}1.7 \text{ mg}/\text{m}^3$  (1–2 ppm) for periods of 1–6 months. Exposure to  $6 \text{ mg}/\text{m}^3$  of diborane resulted in the death of two dogs after 10 and 25 exposures respectively. Seventeen out of 18 rats died during the course of 6 months' exposure.

The median LC50 lethal concentrations for 4-h exposure of rodents to diborane were 80 ppm for 5-month-old and 40 ppm for 2-month-old rats, and 29 ppm for mice [154]. Evidence from an additional experiment with the two different strains of rats suggested that the difference in LC50 values for the rats resulted in a greater measure from the age or weight difference than from the strain difference.

Diborane is rapidly hydrolyzed with release of heat and formation of boric acid in the tissue, but its toxic mechanism is more complex. Golden hamsters were exposed to 11 concentrations from 50 to 1000 ppm of diborane, which had been diluted with nitrogen, to diminish the explosive risk, and compressed air [155]. Each experiment continued until all animals in each group were dead and the time to death was recorded. The test animals quickly became inactive, then restless and increased activity was accompanied by loss of balance. Terminally, respiration decreased in depth and rate with prolonged periods of apnea. From exposures to concentrations up to 400 ppm, the lungs were bright red, and above this concentration dark reddish brown. Vascular congestion, edema, epithelial sloughing, alveolar blood cells and areas of atelectasis and emphysema were present in all animals, more markedly so above 400 ppm. The liver showed no microscopic changes, the kidneys, especially the glomeruli, showed some congestion. A time-concentration curve from 50 to 600 ppm showed progressive shortening of the mean exposure time for death, from 497 to 33 min, and also narrowing of the range around each mean. Above 600 ppm there were no further reductions in minimum, maximum or mean fatal exposure times.

The LC50 of diborane (and that of many other toxic chemicals) depends on the body weight and age of the test animals used [156].

A study of workers subjected to occupational, accidental exposure to diborane extended over a 5-year period (1956–1960) [157]. Among the total of 26 cases of acute diborane toxicity, 18 patients were seen primarily with respiratory involvement. Of

33 patients with subacute exposures, 8 became ill with chest pain. Acute diborane intoxication is associated predominantly with bronchopulmonary involvement, whereas acute decaborane and pentaborane toxicity is manifested primarily by neurological abnormalities. Two cases of acute diborane intoxication with pneumonitis were encountered. Chronic respiratory distress was present in two patients from recurrent diborane exposure and in one patient from repeated borane exposures on three occasions. The clinical symptoms including chest X-rays and the medical treatment were described in detail. The treatment of the acute exposures has been with oxygen by mask or with intermittent positive pressure breathing and the additional use of methocarbamol in many of the cases of pentaborane and decaborane intoxications. Severe neurologic impairment was managed by combined administration of meperidine hydrochloride (Demerol), promethazine (Phenergan), and chlorpromazine (Thorazine) intramuscularly. The chronic cases of diborane were treated with long-term bronchodilators, oxygen with intermittent positive pressure breathing at varying intervals, and expectorants.

Changes in bronchoalveolar lavage fluid (BALF) and blood were examined to assess the toxic effects of diborane on the lungs of rats that were exposed to diborane at 20 ppm (intended concentration) for 4 h (Phase I study) to evaluate time-course changes up to 14 days, and at 10 or 1 ppm to assess the dose-effect relationship after 3 days (Phase II study) [158]. BALF parameters were examined and biochemical and histopathological studies were also carried out. Alveolar capillary and alveolar cell damage were confirmed in rats exposed to 20, 10 or 1 ppm diborane for 4 h. A no-observed-effect level could not be established.

In order to clarify the acute and subacute toxicity of diborane at low concentrations, male ICR mice were exposed to diborane for 1, 2, 4, or 8 h at concentrations of 1 or 5 ppm (Phase I study), and for 6 h/day, 5 days/week, over 2 or 4 week at concentrations of 0.02 or 0.7 ppm (Phase II study) [159]. Hematological and biochemical tests, and histopathological examinations of the cornea, nasal mucosa, respiratory tract, and lung were carried out. All mice in both studies survived until they were sacrificed. In the Phase I study, lung weight increased significantly in mice exposed to 5 ppm of diborane for 8 h. In the Phase II study, slight infiltration of polymorphous neutrophil was observed mainly in the peribronchiolar region in mice exposed to 0.2 or 0.7 ppm of diborane for 2 or 4 weeks. In both studies, hematological and biochemical examinations failed to reveal any exposure-related changes. These results suggested that the no-observed-effect levels of diborane inhalation on the respiratory organs were 1 ppm in acute exposure, but 0.2 ppm of diborane inhalation for 2 or 4 weeks seems to be unsafe.

Diborane acute (15 ppm for 1, 2, 4, or 8 h) and subacute (5 ppm for 2 or 4 weeks) inhalation toxicity studies on mice resulted in a 50% kill after 4-h exposure to 31.5 ppm (interpolated) [160]. Body weight gain was suppressed and the lung weight was increased in diborane-exposed mice in both acute and subacute studies. In the acute study, diffuse bronchiolitis-like lesions developed in the lung in various degrees de-

pending on exposure time, which can be pathologically characterized as infiltration of inflammatory cells into the terminal bronchioles and surrounding alveoli, pulmonary congestion, and bleeding and/or edema. In the subacute study, lymphoid hyperplasia in the perivascular and peribronchial areas, and infiltration of macrophage and plasma cells into the alveoli was detected. In the mice exposed for 4 weeks, the lesions were more severe than in those exposed for 2 weeks, consisting of hyperplasia and desquamation of Clara cells. In the nasal cavity, mucous exudate and inflammatory cells suggested irritation caused by diborane. No significant changes were seen in hematological and serum biochemical examinations. In conclusion, the target organs of diborane inhalation poisoning are the respiratory organs, particularly the lung.

In order to investigate the sequential development of respiratory injuries following acute exposure to diborane, mice were exposed to 15 ppm diborane for 4 h and histopathological, hematological, and serum biochemical examinations were conducted immediately, 1 day, 3 days, and 2 weeks after exposure [161]. Changes progressed most severely on day 3, and lung weight significantly increased with the severity of the pulmonary lesions. At 2 weeks, few inflammatory cells in the bronchiolar lumen remained, and peribronchiolar thickening was disseminated at almost the same sites where inflammatory foci had been detected. The sequential changes in the histopathological observations from this study correlated very well with the clinical signs and symptoms of human acute diborane poisoning cases reported in the 1960s.

### 2.8.2 Olfactory Threshold of Boranes in Air

The median-detectable by odor concentration and the maximum allowable concentration for pentaborane, diborane, and decaborane are listed in Table 5. Diborane can be detected by odor at 2.8–3.6 ppm, but the recommended threshold limit value is 0.1 ppm [155].

**Table 5:** Olfactory threshold of boranes.

| Compound    | Median-detectable concentration |      | Maximum allowable concentration |
|-------------|---------------------------------|------|---------------------------------|
|             | mg/m <sup>3</sup>               | ppm  | ppm                             |
| Pentaborane | 2.5                             | 0.97 | 0.5                             |
| Diborane    | 3.7                             | 3.27 | 1.0                             |
| Decaborane  | 0.35                            | 0.07 | —                               |

Data source: [162]

### 2.8.3 Maximum Allowable Diborane Concentrations

The American Conference of Governmental and Industrial Hygienists revises and updates threshold limit values (TLVs) for hazardous chemicals every year. The 1993–1994 American Conference of Governmental Industrial Hygienists (ACGIH) TLV time-weighted average TWA, the National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL), and the Occupational Safety and Health Administration (OSHA) permissible exposure limits (PEL) for diborane were all identical at 0.1 ppm (0.11 mg/m<sup>3</sup>). Such a low concentration is difficult to measure with the most common continuous analysis equipment. The olfactory threshold of diborane is around 3 ppm, and the human nose is thus not a reliable warning instrument. The NIOSH initially chosen immediately dangerous to life and health (IDLH) limit of 40 ppm was based on the statement by the ACGIH that Jacobson and Lawson (1962) [156] found the rat 4-h LC<sub>50</sub> to be 40 or 80 ppm, depending on the age or strain of rats used. The revised IDLH limit of 15 ppm was chosen on the basis of acute inhalation toxicity data in animals by Krackow (1953) [152]. Table 6 is a summary of diborane toxicity data used by NIOSH in their determination of the IDLH limit [163, 164].

**Table 6:** Lethal concentration (LC) data for diborane inhalation.

| Species | LC <sub>50</sub> (ppm) | LCLo (ppm) | Time   | Adjusted 0.5-h LC (CF) | Derived value | References |
|---------|------------------------|------------|--------|------------------------|---------------|------------|
| Rat     | 40                     | —          | 4 h    | 80 ppm (2.0)           | 8 ppm         | [6, 7]     |
| Mouse   | 29                     | —          | 4 h    | 58 ppm (2.0)           | 5.8 ppm       | [156]      |
| Rat     | 40–80                  | —          | 4 h    | 80–160 ppm (2.0)       | 8 ppm         | [156]      |
| Rat     | 159–181                | —          | 15 min | 126–143 ppm (0.79)     | 13–14 ppm     | [152]      |
| Dog     | —                      | 125        | 2 h    | 200 ppm (1.6)          | 20 ppm        | [165]      |
| Hamster | —                      | 50         | 8 h    | 125 ppm (2.5)          | 13 ppm        | [155]      |

Data source: [166]

### 2.8.4 Personnel Protective Equipment for Handling of Boranes

Candidate materials were screened as to their efficiency for removing boranes from contaminated air streams and to be used in gas masks and air filters [167]. The results of chemical tests and animal exposure studies showed that the following materials give temporary protection against: **(1)** diborane: chemical cartridge respirator charged with hopcalite; **(2)** pentaborane: chemical cartridge respirator charged with activated charcoal; **(3)** pentaborane and decaborane: a combination of silica gel and activated charcoal; and **(4)** diborane, pentaborane, and decaborane: a combination of silica gel, active hopcalite and activated charcoal.

## 2.9 Fire Hazard of Diborane

### 2.9.1 Flammability Limits of Diborane

In general, mixtures of diborane in dry air do not ignite spontaneously at room temperatures, whereas pentaborane spontaneously ignites. No rich limit for pentaborane has ever been established because premature spontaneous ignition of the fuel-air mixture always occurred when attempting to obtain a rich mixture. The autoignition temperature and pressure of diborane in air is quite low, 408 K at 2.15 kPa (135 °C at 16.1 mm Hg) [168].

Because diborane in air may or may not autoignite over a wide range of compositions, it is difficult to determine the limits of flammability. Limits of flammability of diborane in air can be determined only with very lean and very rich mixtures.

Stoichiometric mixtures of diborane in air would contain 6.53 vol.-%  $B_2H_6$ . The lower limit of flammability in a tube measuring 5 cm in diameter at an initial pressure of 300 mm Hg is 0.8 vol.-% and the upper limit is 88 vol.-% [169]. The flammability limits of diborane and pentaborane as a function of fuel:air equivalence ratio and pressure are indicated in Figure 13 in comparison with hydrogen and JP-4 [170]. The rich limit for diborane occurred at an equivalence ratio of about 60, which is about eight times richer than the value for hydrogen, and about 15 times richer than for JP-4.

**Figure 13:** Flammable range of diborane and pentaborane in comparison with other fuels. (Reprinted and modified from [170], with permission from ©1958 Elsevier; permission conveyed through RightsLink.)

### 2.9.2 Explosive Limits in the Oxygen/Diborane System

Diborane gas does not always ignite spontaneously in dry air, but it has been reported that spilled liquid diborane ignited immediately in air. Because diborane and pure oxygen ignite spontaneously on contact, it is difficult to determine the limits of com-

bustibility at atmospheric pressure. Therefore, such measurements were conducted at very low partial pressures, but it is difficult to extrapolate the results to higher pressures such as those encountered in a rocket engine under sea-level starting conditions. It was found that oxygen/diborane gaseous mixtures ignite and explode only after the partial pressures of both reactants exceed a limited partial pressure [168, 171–173]. When diborane is ignited in air there is always a persistent odor characteristic of higher boron hydrides. Thus, it is very probable that in the heat of an explosion some of the diborane is converted to higher, more stable, hydrides and that the stoichiometry of the explosions does not correspond to the equation of complete combustion:

Explosions do occur within a range of composition and pressure, though only at temperatures at or above those corresponding to slow decomposition [168]. The latter strongly suggests sonic interaction with the decomposition process, but no mention is made of anything in the way of an induction period or of an oxygen-sensitized decomposition of diborane. Lower explosion limits were determined by slowly bleeding premixed gases into a clean reaction bulb until explosion occurred. Upper limits were observed by filling the cold reaction bulb to a higher pressure, bringing the thermostatted bath up around the bulb, and then slowly evacuating after a 1.5-min hold. Lower limits were found to be over a range from about 408 to 498 K (135 to 225 °C) for mixtures containing up to 33 vol-% diborane, but no limits could be found for 50% or richer mixtures. In another experiment, crossed streams of diborane and oxygen (presumably at 1 atm) were aimed into a mixing chamber, with gradually rising temperatures. Spontaneous ignition occurred only after the temperature was raised to 405 K (132 °C) or above.

## 2.10 Other Uses for Diborane

Diborane gas is used as a doping agent for the production of semiconductors. It is also an intermediate in the production of highly pure elemental boron for semiconductor production.

## 3 Pentaborane

There are two pentaboranes, pentaborane(9) and pentaborane(11). Pentaborane(9),  $\text{B}_5\text{H}_9$ , CAS RN [19624-22-7], is a volatile liquid that boils at 321 K (48 °C). In the pure state it is a water-clear colorless mobile liquid with a characteristic pungent and nauseating odor. Impurities, such as dissolved polymeric boron hydrides formed from decomposition of other lower boron hydrides present in commercial grade pentaborane, impart a slight yellow discoloration to the liquid if present in concentrations greater than 0.5 mass-%.

There are two known pentaboranes:  $B_5H_9$ , and  $B_5H_{11}$ . Both are colorless liquids. The name *pentaborane* alone is thus not specific as it could refer to either  $B_5H_9$  or  $B_5H_{11}$ . In most cases where no additional number designator is given, the data most often refer to pentaborane  $B_5H_9$ , also often called pentaborane-9 or pentaborane(9). Pentaborane(9) has an extremely disagreeable odor; it decomposes during storage over a long period of time to form hydrogen and a solid, colorless, non-volatile hydride. Pentaborane(11), dihydropentaborane,  $B_5H_{11}$  is less stable than  $B_5H_9$ . It dissociates at room temperature within 24 h to form hydrogen and polymeric solid deposits that stick to the container walls. When discussing properties of  $B_5H_{11}$ , one must always carry the full number designator with its name, pentaborane(11).

Pentaborane is insensitive to mechanical shock and is stable at room temperature under the blanket of an inert atmosphere. Pentaborane is an extremely hazardous rocket propellant owing to its high toxicity, high reactivity, and erratic pyrophoric or spontaneous ignition characteristics. When exposed to air, it may or may not ignite.

### 3.1 Production of Pentaborane

Pentaborane(9) is prepared by pyrolysis of diborane in the presence of excess hydrogen [32, 33, 103, 174]. A small amount of dihydropentaborane is formed along with the desired product, pentaborane(9) [175, 176].

It is difficult to control the diborane pyrolysis process so as to optimize the yields of pentaborane and decaborane and minimize the wasteful formation of unwanted, insoluble high-molecular mass boranes (“yellow solids”) [177].

The pyrolysis of diborane has been studied in single- and multi-pass flow systems to determine the optimal conditions for its conversion to pentaborane [178]. In a single-pass flow system the products consisted of tetraborane, dihydropentaborane ( $B_5H_{11}$ ), pentaborane ( $B_5H_9$ ), decaborane, and undesirable non-volatile solid hydrides. The most economical conversion of diborane to pentaborane was obtained under the following conditions: temperature  $523\text{ K} = 250^\circ\text{C}$ , flow rate  $400\text{ cm}^3/\text{min}$ . and ratio of diborane/hydrogen 1:5 when 15% of the diborane was converted into pentaborane, 4.4% to solid hydrides, and 80% recovered unreacted. In multi-stage reactors designed on the basis of single-pass experiments, the best yield of pentaborane was obtained in a 12-unit reactor operating at  $513\text{ K} = 240^\circ\text{C}$ , flow rate  $400\text{ cm}^3/\text{min}$ , and ratio diborane/hydrogen 1:5. Under these conditions, 57% of the diborane was converted into pentaborane, 14% to solid hydrides, and 29% was recovered unchanged.

Pentaborane(11) is an intermediate in the production of pentaborane(9). The production of pentaborane(11) was successfully scaled up to the point where about  $0.75\text{ cm}^3$  per min could be produced in runs lasting 10–20 min. by allowing diborane at 172 kPa (25 psig) to flow at 8 L/min. through a 16-L reactor maintained at  $393\text{ K}$  ( $120^\circ\text{C}$ ) [179].

## 3.2 Physical Properties of Pentaborane

### 3.2.1 Freezing Point, Boiling Point, and Critical Point of Pentaborane

The physical properties of pentaborane are summarized in Table 7.

**Table 7:** Physical properties of pentaborane(9).

| Property                       | SI units        | Other units | References |
|--------------------------------|-----------------|-------------|------------|
| Molecular mass                 | 63.126          |             | [53]       |
| Freezing point                 | 226.42 K        | −46.75 °C   | [60]       |
|                                | 226.41 ± 0.02 K | −46.74 °C   |            |
| Boiling point                  | 333.21 K        | 60.06 °C    | [180]      |
|                                | 331.5           | 58.4 °C     |            |
| Index of refraction $n_D^{24}$ | 1.4445          | —           | [60]       |
| Critical temperature           | 497 K           | 224 °C      | [1]        |
| Critical pressure              | 3.84 MPa        | 557 psia    | [1]        |

The melting point of pentaborane was found to be  $226.41 \pm 0.02$  K (−46.74 °C), and the purity as determined from fraction melted versus temperature curves was 99.9 mol-% [181].

### 3.2.2 Vapor Pressure of Pentaborane

The vapor pressure of pentaborane within the temperature range 226–298 K is given by the equation [181]:

$$\log p = 9.96491 - \frac{1951.14}{T} - 0.003688T,$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The vapor pressure between 298 and 348 K (25 and 75 °C) can be calculated from the following curve-fitted equation [182]:

$$\log p_D = 5.6352 - \frac{1384}{t + 250},$$

where  $p_D$  is the vapor pressure in psia and  $t$  is the temperature in °C. For higher temperatures from 348 to 398 K (75 to 125 °C), a slightly different equation was recommended:

$$\log p_D = 4.4803 - \frac{730}{t + 160},$$

where again  $p_D$  is the vapor pressure in psia and  $t$  is the temperature in °C. The vapor pressure of pentaborane as a function of temperature is illustrated in Figure 14. The vapor pressure changed a little after the volatiles were pumped off.

**Figure 14:** Vapor pressure of pentaborane as a function of temperature. (Reproduced and modified from [180].)

### 3.2.3 Density of Pentaborane

Density data for liquid pentaborane are listed in Table 8.

**Table 8:** Density of liquid pentaborane.

| Temperature |       | Density           |
|-------------|-------|-------------------|
| K           | °C    | g/cm <sup>3</sup> |
| 226.9       | -46.2 | 0.681             |
| 227         | -46.1 | 0.681             |
| 235.2       | -37.9 | 0.675             |
| 235.4       | -37.7 | 0.675             |
| 246.1       | -27   | 0.666             |
| 253         | -20.1 | 0.66              |
| 263.2       | -9.9  | 0.652             |
| 274.6       | 1.5   | 0.642             |
| 283.5       | 10.4  | 0.635             |
| 289.3       | 16.2  | 0.63              |

Data source: [52]

The data in Table 8 above can be described by the following equation:

$$\rho = 0.8674 - 0.00082T,$$

where  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin. The density of liquid pentaborane from 288 to 388 K (15 to 115 °C) can also be described by the following equation:

$$\rho = 0.6404 - 0.000883t,$$

where  $\rho$  is density in  $\text{g}/\text{cm}^3$  and  $t$  is temperature in °C [183]. The density of liquid pentaborane between 265 and 298 K (−8 and +25 °C) was measured and curve-fitted by the equation:

$$\rho = 0.637 - 0.000733t,$$

where  $\rho$  is density in  $\text{g}/\text{cm}^3$  and  $t$  is temperature in °C [184]. The measured density at 273 K (0 °C) was  $0.637 \pm 0.002 \text{ g}/\text{cm}^3$ . The maximum deviation of any measured point from the curve-fitted curve was  $\pm 0.05\%$ . The raw density data points from which this curve-fitted equation was derived are shown in Figure 15.

**Figure 15:** Density of liquid pentaborane as a function of temperature. (Reproduced and modified from [180].)

Individual density data points reported by other sources are  $0.638 \text{ g}/\text{cm}^3$  at 273 K and  $0.623 \text{ g}/\text{cm}^3$  at 293 K [180].

3.2.4 Viscosity of Pentaborane

The viscosity of liquid pentaborane from 273 to 388 K (0 to 115 °C) can be described by the following equation:

$$\log \eta = \frac{344.75}{T} - 1.45851,$$

where  $\eta$  is the viscosity in centistokes, and  $T$  is temperature in K [183].

The viscosity of liquid pentaborane was measured over a range of temperatures from 245 to 313 K (–28 to 40 °C) (Table 9 and Figure 16). It was found necessary, however, to discard all values taken above 293 K (20 °C) as polymerization or some

Table 9: Viscosity of liquid pentaborane.

| Temperature |       | Density           | Viscosity  |
|-------------|-------|-------------------|------------|
| K           | °C    | g/cm <sup>3</sup> | millipoise |
| 232.2       | –40.9 | 0.6766            | 7.82       |
| 245.0       | –28.1 | 0.6662            | 5.29       |
| 246.5       | –26.6 | 0.6651            | 5.64       |
| 253.2       | –19.9 | 0.6598            | 5.14       |
| 258.4       | –14.7 | 0.6554            | 4.78       |
| 264.1       | –9.0  | 0.6509            | 4.45       |
| 269.0       | –4.1  | 0.6468            | 4.17       |
| 274.1       | 1.0   | 0.5426            | 3.94       |
| 279.6       | 6.5   | 0.6382            | 3.68       |
| 286.4       | 13.3  | 0.6326            | 3.42       |

Data source: [52]

Figure 16: Viscosity of liquid pentaborane. (Reproduced and modified from [180].)

other phenomenon occurred above this temperature to increase the viscosity quite markedly.

The viscosity of liquid pentaborane, the same data as shown in Table 9 and Figure 4, as a function of temperature, can be expressed by the equation [52]:

$$\eta = 41.15 \times 10^{-5} \rho^{\frac{1}{3}} e^{\left(\frac{1024}{\rho T}\right)},$$

where  $\eta$  is the viscosity in Poise,  $\rho$  is the density in  $\text{g}/\text{cm}^3$ , and  $T$  is the temperature in kelvin. See also Wirth and Palmer for additional viscosity data [181].

### 3.2.5 Surface Tension of Pentaborane

The surface tension of pentaborane was measured within the range 234 to 303 K (−39 to +30 °C). An illustration of the surface tension data was already shown in Figure 6 (above in the diborane section). The numeric surface tension data are listed in Table 10.

The data in Table 10 can be fitted to a linear equation:

$$\sigma = (71.1 - 0.143T)\rho^{\frac{2}{3}},$$

where  $\sigma$  is the surface tension in  $\text{dyn}/\text{cm}$ ,  $\rho$  is the density in  $\text{g}/\text{cm}^3$  and  $T$  is the temperature in kelvin. Surface tension data from the same source are graphed in Figure 17.

**Table 10:** Surface tension of pentaborane.

| Temperature |       | Surface tension |        |
|-------------|-------|-----------------|--------|
| K           | °C    | mN/m            | dyn/cm |
| 233.9       | −39.2 | 28.9            | 28.9   |
| 245.1       | −28   | 27.4            | 27.4   |
| 249.0       | −24.1 | 27.0            | 27.0   |
| 259.3       | −13.8 | 25.6            | 25.6   |
| 264.7       | −8.4  | 24.8            | 24.8   |
| 269.5       | −3.6  | 24.5            | 24.5   |
| 286.2       | +13.1 | 22.0            | 22.0   |
| 294.4       | +21.3 | 21.2            | 21.2   |
| 303.3       | +30.2 | 20.1            | 20.1   |

Data source: [52]

1 N =  $10^5$  dyn

**Figure 17:** Surface tension of pentaborane. (Reproduced and modified from [180], based on data from [181].)

### 3.2.6 Thermal Conductivity of Pentaborane

The thermal conductivity of liquid pentaborane from 294 to 314 K (70 to 105 °F) can be described by the following equation:

$$\kappa = 0.0874 - (0.0000684 \times t)$$

where  $\kappa$  is the thermal conductivity in  $\text{BTU h}^{-1} \text{ft}^{-2}$ , and  $t$  is the temperature in °F [182].

### 3.2.7 Heat Transfer to Liquid Pentaborane

Callery Chemical Co. conducted heat transfer experiments with liquid pentaborane at 1 to 3.4 MPa (145–495 psia), bulk temperatures 288 to 330 K (519–595°R), flow velocities of 6 to 19 m/s, and heat fluxes of up to  $326 \text{ W/cm}^2 = 78 \text{ cal cm}^{-2} \text{ s}^{-1}$  and discovered that pentaborane is not suitable as a coolant in regeneratively cooled rocket engines at high heat loads because the metal surface is quickly covered with solid deposits that reduce the heat transfer and in real life in a rocket engine would lead to burnout of the nozzle and chamber wall [185]. The wall temperature was limited to 394 K (710°R) [186].

### 3.2.8 Electric and Magnetic Properties of Pentaborane

In contrast to diborane, pentaborane is a highly polar substance, with an apparent dipole moment of the liquid varying between 3.37 Debye at room temperature to 4.54 Debye at the melting point. Within the temperature range 130–140 K there is a sluggish solid-solid phase transition that may be accompanied by the onset of free rotation in the solid [181]. The dielectric constant of pentaborane as a function of temperature is illustrated in Figure 18.

**Figure 18:** Dielectric constant of pentaborane as a function of temperature. (Reproduced and modified from [180].)

Nuclear (proton) magnetic resonance is the preferred way to identify the difference between hydrogen atoms in boron hydrides, depending on if they are part of a bridge structure or not. From nuclear magnetic resonance (NMR) data obtained for pentaborane, ethylpentaboranes, and  $^{13}\text{C}$ -enriched methylpentaboranes, estimates of differences in cage-boron charges and electronegativities can be made [187, 188]. The extra hydrogen that makes the difference between pentaborane(9) and pentaborane(11) is in a particularly labile (“anomalous”) position [189, 190].

### 3.2.9 Critical Point Parameters of Pentaborane

The critical temperature of pentaborane, calculated from theoretical calculations, is 500 K = 227 °C. In real life, pentaborane is unstable and would have decomposed a long time before reaching this temperature.

### 3.2.10 Solubility of Pressurant Gases

The solubilities of nitrogen, hydrogen, and helium in liquid pentaborane at 3.5, 7, and 10.5 MPa (500, 1000, and 1500 psig) from 303–423 K (30–150 °C) were reported [183].

### 3.2.11 Thermodynamic Properties of Pentaborane

The thermodynamic properties of pentaborane are listed in Table 11.

**Table 11:** Thermodynamic properties of pentaborane.

|                                 | SI units                                | Other units                                  | References |
|---------------------------------|-----------------------------------------|----------------------------------------------|------------|
| Molar heat capacity at 298 K    | 151 J mol <sup>-1</sup> K <sup>-1</sup> | 36.12 cal mol <sup>-1</sup> °C <sup>-1</sup> |            |
| Standard enthalpy of formation  | +42.8 ± 6.7 kJ/mol                      | +10.24 ± 1.6 kcal/mol                        |            |
| $\Delta H_f^{298}$ liquid       | +32.6 kJ/mol                            | +7.8 kcal/mol                                | [180]      |
|                                 | +32.38 ± 1.76 kJ/mol                    | +7.74 ± 0.42 kcal/mol                        | [191]      |
| Standard enthalpy of formation  | +73.2 ± 6.7 kJ/mol                      | +17.5 ± 1.6 kcal/mol                         |            |
| $\Delta H_f^{298}$ gaseous      | +62.8 kJ/mol                            | +15.0 kcal/mol                               | [180]      |
|                                 | +62.84 ± 1.67 kJ/mol                    | +15.02 ± 0.4 kcal/mol                        | [191]      |
| Heat of fusion at melting point | 6.14 kJ/mol                             | 1.468 kcal/mol                               |            |
| Heat of evaporation             | 30.5 kJ/mol                             | 7.28 kcal/mol                                |            |
| at 298 K = 25 °C                |                                         |                                              |            |
| Heat of evaporation             | 32.2 kJ/mol                             | 7.7 kcal/mol                                 | [180]      |
| at normal boiling point         |                                         |                                              |            |
| Enthalpy of phase change        | 1.8 kJ/mol                              | 0.430 kcal/mol                               |            |
| at 136.6 K = -136.5 °C          |                                         |                                              |            |
| Heat of combustion, liquid      | 4294 kJ/mol                             | 1026.4 kcal/mol                              | [180]      |

The heat of formation of pentaborane was determined by measurements of the heat of decomposition into amorphous boron and hydrogen in a calorimeter [90]. The heat of formation at 298 K (25 °C) from amorphous boron and hydrogen was +54.4 ± 1.6 kJ/mol (+12.99 ± 0.39 kcal/mol) for pentaborane (gas) and +23.8 ± 1.6 kJ/mol (+5.69 ± 0.40 kcal/mol) for liquid pentaborane.

The heat capacity of pentaborane vapor as a function of temperature can be calculated from the Shomate Equation:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p$  is the heat capacity in J mol<sup>-1</sup> K<sup>-1</sup>, A, B, C, D, and E are constants, and  $\tau$  is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 12. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation of the vapor. These equations were curve-fitted from data covering ranges from 1500 to 6000 K. Of course at those temperatures pentaborane would long since have decomposed into the elements.

**Table 12:** Constants for vapor phase thermodynamic properties of pentaborane.

| Temperature range, K | 1500–6000 |
|----------------------|-----------|
| A                    | 302.0563  |
| B                    | 16.13748  |
| C                    | –3.133799 |
| D                    | 0.210327  |

Data source: [53]

The vapor phase or liquid phase excess enthalpy above the standard enthalpy of formation  $\Delta H_f^{\circ 298}$  of pentaborane can be calculated from the Shomate Equation:

$$H^{\circ} - H_{298.15}^{\circ} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where A, B, C, D, E, and F are constants, and  $\tau$  is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 12 (vapor phase) and Table 13 (liquid phase).

**Table 13:** Constants for thermodynamic properties of liquid pentaborane.

| Temperature range, K | 298–700   | 700–1500  |
|----------------------|-----------|-----------|
| A                    | 1777.865  | –50.81426 |
| B                    | –6068.264 | 647.6665  |
| C                    | 8247.877  | –432.3746 |

| F                    | –419.1448 | 55.06353  |
| H                    | 42.84416  | 42.84416  |

Data source: [53]

Additional physical properties of pentaborane are summarized in [180] and [192].

### 3.2.12 Optical, Electrical, and Magnetic Properties of Pentaborane

#### 3.2.12.1 Infrared Spectra of Pentaborane

The IR spectra of pentaborane are important for deriving thermodynamic properties and thermodynamic properties are important for calculating theoretical specific impulse of rocket engines with pentaborane. IR spectra of pentaborane are important for assuring the purity of the product and for identifying unwanted contaminants. Penta-

borane has been subjected to group theoretical reduction considerations to ascertain which overtone frequencies are IR active for this molecule. Ten bands were observed in the IR spectrum of liquid pentaborane. The pentaborane molecule is believed to belong to the  $C_{4v}$  symmetry group, as determined by electron and X-ray diffraction data. Assuming this symmetry point group and applying the usual group theoretical reduction methods, most bands could be assigned to fundamental vibrations [73]. On the basis of the data obtained, bond energies, bond distances, and force constants have been calculated for the B—H bonds in each of the three boranes.

Deuterated pentaborane can be prepared by catalytic exchange accelerated by a chromia-alumina catalyst between  $B_5H_9$  and excess deuterium at room temperature [193]. The vibrational modes of several fundamentals in the IR absorption spectra of gaseous  $B_5H_9$  and  $B_5D_9$  were identified by consideration of B isotopic band structure and the frequency shift on deuteration and assignment of the fundamental frequencies was possible.

The IR and the Raman spectra of liquid deuterated pentaborane, which was prepared by the catalytic exchange of normal pentaborane and deuterium, were measured and the polarization of the stronger Raman lines was determined [194] (Figure 19). Spectra of  $B_5H_9$  were recorded at two different pressures, 12 mm Hg (top trace) and 150 mm Hg (bottom trace). Based on these spectra, assignments of the vibrational frequencies of normal and deuterated pentaborane could be made, and the correlation of normal frequencies in deuterated and non-deuterated molecules was discussed. The thermodynamic functions of normal pentaborane vapor were calculated for the temperature range 296 to 2500 K from these assignments.

**Figure 19:** Infrared spectrum of pentaborane in the NaCl region. (Reproduced and modified from [194].)

### 3.2.12.2 Raman Spectra of Pentaborane

The Raman spectra of  $B_5H_9$  were recorded for the gas and liquid phases [195]. Moderately high resolution IR spectra of the gas phase were also recorded and then combined with the Raman data to assign natural isotopic data and verify previously proposed vibrational assignments [196].

### 3.2.13 Molecular Structure of Pentaborane

Pentaborane is a symmetric top molecule with a large dipole moment of 2.13D in the direction of the symmetry axis. The pentaborane structure has five atoms of boron arranged in a square pyramid. Each boron has a terminal hydride ligand and four hydrides span the edges of the base of the pyramid (Figure 20). Note that each of the three images in Figure 20 shows the molecule from a different angle of view. The ball-and-stick diagram in the center shows the molecule “from below” with the apex pointing away.

**Figure 20:** Molecular structure of pentaborane(9).

Sometimes the position of the boron and hydrogen atoms are designated as **apical**, **ring**, **terminal**, or **bridge** by using the subscripts  $a$ ,  $r$ ,  $t$ , or  $\mu$ , respectively (Figure 21). The complete structure is determined by seven structural parameters.

**Figure 21:** Atom position designations in pentaborane(9).

The structure of pentaborane(9) has been investigated by XRD, electron diffraction and microwave absorption spectra. However, in all these studies the hydrogen positions were obtained only with large uncertainties. The investigation of the rotational spectra of the deuterated isotopes provided a more accurate method of determining the bridge hydrogen structure [197]. The microwave spectra of 15 isotopic species of  $B_5H_9$  were investigated. The complete molecular structure was determined from these data by assuming  $C_{4v}$  symmetry:  $B_r \cdots B_r = 1.803 \pm 0.002 \text{ \AA}$ ;  $B_r - B_a = 1.690 \pm 0.002 \text{ \AA}$ ;  $B_r - H_t = 1.186 \pm 0.002 \text{ \AA}$ ;  $B_a - H_a = 1.181 \pm 0.002 \text{ \AA}$ ;  $B_r \cdots H_\mu = 1.352 \pm 0.004 \text{ \AA}$ ;  $\angle B_a - B_r - H_t = 128.72 \pm 0.55^\circ$ ;  $\angle \phi = 193.10 \pm 2.9^\circ$ . Evidence is given of a large vibrational amplitude for the bridge hydrogens.

A study of free electron distributions in a hemispherical box and a hemispherical shell, and a study of simplified LCAO models for  $B_5H_9$  and  $B_5H_{11}$  indicated an uneven charge distribution in these unsymmetrical molecules [198].

The dipole moment of pentaborane(9) is  $2.13 \pm 0.04$  Debye [199]. The microwave spectra gave B—B distances of  $1.69 \pm 0.02 \text{ \AA}$  (ring-apex) and  $1.80 \pm 0.01 \text{ \AA}$  (ring-ring).

On cooling through the 136.7 K phase transition, the tetragonal unit cell of  $B_5H_9$  transforms to a tetragonal cell whose  $a$  and  $b$  axes correspond to the  $ab$  diagonals of the high temperature cell, and the  $c$ -axis is doubled [200]. The low temperature cell contains eight molecules,  $a = b = 10.201(5) \text{ \AA}$ ,  $c = 9.996(5) \text{ \AA}$ , space group  $P4_1$ .

### 3.3 Chemical Properties of Pentaborane

At a time when the US Government purchased pentaborane for high-energy fuels (mostly air breathing fuels) research and development, the procurement of pentaborane was covered by Military Specification MIL-P-27403(USAF) – Propellant, Pentaborane [201].

This specification required an assay of at least 99 mass-% (determined by a freezing point method), limited dissolved solids to a maximum of 1.1 mass-%, and specified a thermal stability of at most 1.5 mass-% decomposing in a vacuum evaporation apparatus. Some of the chemical properties of pentaborane are summarized in a very useful summary report [180].

#### 3.3.1 Reactions of Pentaborane

One would think that dinitrogen is an inert gas and it should be possible to use nitrogen as a pressurant gas for expulsion of pentaborane without any undue interaction. However, apparently at higher temperatures pentaborane will react even with dinitrogen, which until now was always considered an inert gas.

### 3.3.1.1 Hydrolysis of Pentaborane

Pentaborane does not hydrolyze as rapidly as diborane. Based on mass-spectrometric analysis of reaction products, the first step in the hydrolysis may be the removal of a borine  $\text{BH}_3$  from the cluster of  $\text{B}_5\text{H}_9$  [202]. Water and pentaborane are not miscible and the hydrolysis would take place only at the interphase of the two layers. If the two layers are dissolved in a mutually miscible solvent like dioxane, the hydrolysis reaction becomes very fast, near-catastrophically fast [203]:

The hydrolysis proceeds only at elevated temperatures (358 to 423 K = 85 to 150 °C) with measurable speed. Kinetic investigations have shown that in the presence of an excess of water, the reaction then proceeds as a first-order reaction with respect to pentaborane [204]. Pentaborane hydrolyzes with water to form hydrogen and boric acid [126, 205]. If an accidental spill of pentaborane ignites, the question is whether water is a suitable extinguishing agent or whether it will make matters worse by releasing hydrogen gas, which of course will burn too.

### 3.3.1.2 Reactions of Pentaborane with Lewis Bases

Reactions of pentaborane with amines lead to destruction of the pentaborane molecule and formation of fragments. At 195 K (−78 °C) pentaborane adds  $\text{Me}_3\text{N}$  to form  $\text{B}_5\text{H}_9 \bullet 2\text{Me}_3\text{N}$ , which on heating under vacuum will partially dissociate to the original components and partially decompose to  $\text{BH}_3\text{N}(\text{CH}_3)_3$  and  $(\text{BH})_x$  [206]. Bases strong enough for irreversible attachment to  $\text{BH}_3$  “steal”  $\text{BH}_3$  from  $\text{B}_5\text{H}_9$  [207].

Ammonia or methylamine, reacting with pentaborane(9) during sudden heating at 433–453 K (160–180 °C), can displace as much as 0.25 mol of  $\text{B}_2\text{H}_6$  per mole of  $\text{B}_5\text{H}_9$  consumed [208]. The reason for such anomalous behavior, whereby strong molecular bases displace a strong Lewis acid, is to be found in a series of reaction steps whereby the base first disrupts the  $\text{B}_5\text{H}_9$  to combine with the  $\text{B}_4\text{H}_6$  and  $\text{BH}_3$  fragments. Next, the  $\text{BH}_3$  complex makes borazane and hydrogen, then borazane accepts a second  $\text{BH}_3$  to make a  $\mu$ -aminodiborane, which finally dissociates into diborane and the borazane trimer, the latter at last going to the corresponding borazine.

These Lewis acid-Lewis base reactions are strongly exothermic and in the case of hydrazine can result in ignition and a new type of bipropellant rocket propellant combination that does not involve traditional oxidizers [209–211].

Pentaborane reacts with ammonia to form salt-like compounds, which are stable at room temperature [212]:

### 3.3.1.3 Reactions of Pentaborane with Strong Bases

Pentaborane is a weak acid and forms salts with potassium hydroxide, resulting in deprotonation [213, 214]. The potassium pentaborate salt is soluble in tetrahydrofuran.

### 3.3.1.4 Reactions of Pentaborane with Organic Compounds

Ethylene adds to pentaborane in an autoclave in the presence of aluminum chloride as a Friedel-Crafts catalyst, forming ethylpentaborane [215, 216]. Friedel-Crafts ethylation of pentaborane-9 with ethylene/aluminum chloride gave only monoethylpentaborane and there was no evidence of polysubstitution. Better yields of ethylpentaborane were obtained with lower ethylene pressures. The ethylpentaborane could be separated from unreacted pentaborane by fractionated distillation under a small positive pressure of nitrogen.

The Friedel-Crafts alkylation of pentaborane with ethylene/aluminum chloride in a heated Nimonic autoclave gave yields of 20 to 35% at 323 K (50 °C) with an ethylene pressure of 552 kPa (80 psi) [216–218].

The hydrogen atom at the apex of the pentaborane-9 molecule can be replaced by alkyl groups by reaction with alkenes or alkyl halides in the presence of Lewis acids such as  $\text{AlCl}_3$ ,  $\text{FeCl}_3$  or  $\text{SnCl}_4$  [219]. The mechanism appeared to be an electrophilic substitution. The following alkylpentaboranes have been prepared and characterized: 1-methylpentaborane, 1-ethylpentaborane, 1-isopropylpentaborane, and 1-*sec*-butylpentaborane.

The reaction of olefins with pentaborane-9 at 423 K (150 °C) gave the alkyl derivatives of pentaborane-9, with substitution at a base boron atom [220, 221]. *n*-Butyl-, *sec*-butyl-, isobutyl-, and ethylpentaborane could be prepared in this way. The direction of addition on the olefins, the position of substitutions on pentaborane-9, and the reactivity of the olefins were in accord with the expectations of a reaction involving a nucleophilic attack of olefins on pentaborane-9.

The reaction of pentaborane with acetylene leads to closo-carboranes [222]. See also [223].

### 3.3.1.5 Slow Oxidation of Pentaborane

Intermediates of the autoignition reaction can be trapped and identified if the reaction is slowed down by dilution with inert gases or carried out at lower temperatures and lower pressures. An intermediate compound of the slow oxidation of pentaborane had the composition  $\text{B}_2\text{H}_2\text{O}_3$  in which each H atom is attached directly to a B atom and in which the 2 B atoms exist in identical configurational environments [224].

The heat evolved during slow oxidation of pentaborane pyrolyzes unreacted pentaborane and forms a little diborane in a reversal of the traditional pentaborane synthesis. When dry air was admitted to a vessel containing pure pentaborane at 298 K and 6.7 kPa, partial oxidation took place and diborane, hydrogen and a white solid were formed [225]. The slow oxidation of pentaborane is accompanied by bluish light emission preceding a flame reaction [226].

A mass spectrometric technique was used to follow the stoichiometry of the slow oxidation of  $B_5H_9$  as oxygen was slowly added to a borane sample at pressure between (5 and 20 mm Hg) [227]. In the  $O_2/B_5H_9$  reaction boroxine ( $H_3B_3O_3$ ) was formed initially and further oxidation gave  $H_2B_2O_3$ . Results of isotope distribution experiments indicated that the precursor to  $H_3B_3O_3$  (and  $H_2B_2O_3$ ) in the  $O_2/B_5H_9$  reaction was probably HBO or  $H_2BOH$ . See also [228] and [229].

Rates of pyrolysis of pentaborane and ignition induction times of oxygen/pentaborane/argon mixtures were measured in a shock tube at 520 to 860 K [230]. The effects of pressure, mixture ratio, and a variety of additives on the flame speed of the pentaborane-air system were studied employing a low-pressure burner. Pyrolysis of pentaborane was shown to be the rate-controlling step in the ignition process, as induction times were independent of oxygen concentration. Butadiene, toluene, and benzene were most effective in reducing flame speed and in lengthening ignition induction times. The order of inhibitor effectiveness on the flame reaction bears a close resemblance to that of the air/hydrogen and air/diborane flame systems, indicating that flame propagation in the air/borane system may proceed by a mechanism resembling, to some extent, that of the oxygen/hydrogen where inhibitors function by removal of hydrogen atoms from the pre-flame zone.

### 3.3.2 Thermal Stability of Pentaborane

Pentaborane lacks thermal stability and at temperatures between 358 and 475 K (85 to 202 °C) decomposes in the course of a few days to hydrogen, a non-volatile solid boron hydride, and traces of decaborane [231, 232].

The thermal stability of  $B_5H_9$  was determined as the rate of pressure increase in 800-mL test cylinders filled to 7% ullage and was stored at different temperatures. In storage containers with insufficient ullage, for instance 7% ullage, the decomposition product pressure can increase to 8.27 MPa (80 atm = 1200 psig) within 3 h at 423 K (150 °C), 28 h at 398 K (125 °C) or 360 h at 373 K (100 °C), which may result in rupture of the vessel, depending on its pressure rating [233]. At 439 to 489 K (166 to 216 °C) the decomposition of pentaborane proceeded quite rapidly. At long hold times and high temperatures the predicted percentage decomposition was higher than the observed percentage decomposition. Investigations were made to determine the effects of added dihydrogen and  $B_{10}H_{14}$  on pentaborane thermal stability after 138 h, at a temperature of 383 K (110 °C) and an ullage of 52%. The addition of 26.8 mol-% dihydrogen (approximately 1175 psig) for one test and 9.2 mol-%  $B_{10}H_{14}$  for another test resulted in 6.5 and 8.1% decomposition respectively, whereas a blank  $B_5H_9$  control test resulted in 10.3% decomposition.

The formation of polymeric boron hydrides during storage of pentaborane must be kept at a minimum as precipitation of these solids tends to clog filters and valves during transfer or injector orifices in a rocket chamber. It was found that these non-volatile solids precipitate out at a concentration of 3 mass-% at 383 K (110 °C) and

1.3 mass-% at 80 °C. Dissolved solids in commercial grade pentaborane have been found as high as 1.3 mass-%. Approximately 25% of the precipitated solids may be decaborane.

The pyrolysis of pentaborane(9) was studied at 475, 486.6, and 501 K (202, 213.5, and 228 °C) at a pressure of about 5.33 kPa (40 mm Hg) and at 477 K (204 °C) at a pressure of about 10.7 kPa (80 mm Hg) [234]. The reaction was found to be first order and rate constants were  $1.68 \pm 0.03 \times 10^{-6}$ ,  $1.79 \pm 0.05 \times 10^{-6}$ ,  $2.62 \pm 0.2 \times 10^{-6}$ , and  $8.23 \pm 0.1 \times 10^{-6} \text{ s}^{-1}$  at 475, 477, 486.6, and 501 K (202, 204, 213.5, and 228 °C) respectively. The activation energy was  $130 \pm 6.3 \text{ kJ/mol}$  ( $31.1 \pm 1.5 \text{ kcal/mol}$ ). These results agreed relatively well with the values reported by Cheney et al. [235]. They obtained first-order rate constants of  $0.376 \times 10^{-2}$ ,  $1.73 \times 10^{-2}$ ,  $4.18 \times 10^{-2}$ , and  $11.6 \times 10^{-2} \text{ h}^{-1}$  at 467.6, 489.1, 501.6, and 516.1 K (194.5, 216, 228.5, and 243 °C) respectively, and an activation energy of  $142 \pm 4 \text{ kJ/mol}$  ( $33.9 \pm 1 \text{ kcal/mol}$ ). Converting the rate constants to common units gave rate constants of  $4.8 \times 10^{-6}$  and  $1.16 \times 10^{-5} \text{ s}^{-1}$  at 489.1 and 501.6 K (216 and 228.5 °C) respectively, which are approximately 20% larger than the rate constants reported by [234].

A mass spectrometer with an integral flow reactor was used to study the pyrolysis of  $\text{B}_5\text{H}_9$  and  $\text{B}_5\text{H}_{11}$  at very low pressures and to measure their molecular beam mass spectra [236]. The room-temperature molecular beam mass spectrum of  $\text{B}_5\text{H}_9$  agreed with the spectrum obtained with an instrument with a conventional ion source. The molecular beam mass spectrum of  $\text{B}_5\text{H}_{11}$  differed slightly from the conventional, but there were indications of contributions to the latter by pyrolysis products formed in the ion source. A study of the pyrolysis of  $\text{B}_5\text{H}_{11}$  has shown  $\text{B}_4\text{H}_8$  and  $\text{BH}_3$  to be decomposition products. No triborane species could be observed. Diborane and pentaborane(9) were seen, but no higher boranes could be detected under these experimental conditions.

The kinetics of homogeneous thermal decomposition of pentaborane(11) were investigated by a mass-spectrometric technique in the pressure range 1.75–10.5 mm Hg and temperature range 313–423 K (40–150 °C) and found to proceed by a first-order initial-rate gas-phase process. The main volatile products were dihydrogen, diborane, and a little pentaborane(9) [237]. In the thermolysis of  $\text{B}_5\text{H}_{11}$  there was a dramatic change in product distribution, but the order, activation energy, and initial rate of disappearance of  $\text{B}_5\text{H}_{11}$  were all unaffected by the presence of added dihydrogen [238].

The thermal stability of the various boranes has been ranked as follows:  $\text{B}_5\text{H}_9$  more stable than  $\text{B}_2\text{H}_6$  by a factor of 100;  $\text{B}_2\text{H}_6$  more stable than  $\text{B}_5\text{H}_{11}$  by a factor of 10,  $\text{B}_5\text{H}_{11}$  more stable than  $\text{B}_4\text{H}_{10}$  by a factor of 5.

### 3.3.3 Photolysis of Pentaborane

It was hoped that photolysis of pentaborane would lead to some other, more energetic or heretofore unknown boranes, but in reality the photolysis of pentaborane leads to a mix of several boranes that are difficult to separate. Pentaborane vapor at 20 mm Hg

was illuminated with the UV light from a hydrogen lamp. The rate of conversion was measured by IR absorption and an increase in total pressure owing to evolved hydrogen. The rate of conversion decreased with time as it approached a stationary equilibrium owing to reversible reactions. Added hydrogen would retard the reaction [239].

Illumination of  $B_5H_9$  in the gas phase by ArF laser radiation at 193 nm caused primary dissociation into  $BH_3$  and  $B_4H_6$  [240]. A reactive intermediate  $B_5H_7$ , upon addition to  $B_5H_9$ , forms  $B_{10}H_{14}$  and  $B_{10}H_{16}$ .  $B_6H_{10}$  formation as well as polymerization may proceed via the intermediate  $B_8H_{12}$ , which arises from the dimerization of  $B_4H_6$  fragments. See also [114] and [241].

### 3.3.4 Analysis of Pentaborane

#### 3.3.4.1 Physical Methods for Analysis of Pentaborane

For quick-look data, the density, vapor pressure, and freezing point of pentaborane(9) may all be determined in a quality control laboratory with one basic transfer apparatus and test vessels of 1–5 mL in volume. These physical properties plus a determination of dissolved and total solids (hydrolysis products) are sufficient to certify that the pentaborane is suitable for use in a rocket engine but may not be sufficient if pentaborane is to be used for the synthesis of other fuels [180]. The freezing point depression in the presence of contaminants is an indication of the purity of a sample of pentaborane. The purity of  $B_5H_9$  could be determined within 10 mol-% on sample sizes of 2–10 mL. One of the possible contaminants is decaborane, which forms as a byproduct during the production of pentaborane from diborane.

#### 3.3.4.2 Methods for Analysis of Assay and Contaminants in Pentaborane

Gas chromatographic methods are quite suitable for the analysis of boron hydrides [129, 130].

Mixtures of pentaborane with other boron hydrides can be analyzed by IR-spectrometric methods, as the spectra of individual boranes are pretty well known. A method was developed for the determination of the four constituents, diborane, tetraborane, and dihydropentaborane in a relatively larger amount of pentaborane [73, 132]. The infrared spectrum of pentaborane was obtained from 2 to 15  $\mu\text{m}$  at 100 mm Hg pressure, and the concentrations of diborane, tetraborane, pentaborane, and dihydropentaborane were determined based on their absorption at specific wavelengths: 4.05, 4.65, 5.54, and 6.15  $\mu\text{m}$ . Base line points are chosen at 3.50 and 5.92  $\mu\text{m}$ . The spectrum must be obtained rapidly to prevent decomposition. The equations permit the direct calculation of the pressure in mm Hg for each boron hydride from measurement of the absorption at four wavelengths, 4.05, 4.65, 5.54, and 6.35  $\mu\text{m}$ . At a total pressure of 100 mm Hg, the minimum detectable amount of diborane was about 0.2 mol-%, for tetraborane it was 0.6 mol-% and for dihydropentaborane it was 0.7 mol-%.

For the determination of assay of pentaborane samples, pentaborane can be reacted with ethanol and the hydrogen gas evolved can be measured gas volumetrically [242]:

This reaction has also been proposed for the disposal of surplus pentaborane. See also [243].

### 3.3.4.3 Detection of Pentaborane in Workroom Air

Work room air must be monitored to ensure a safe working environment where pentaborane is used and stored. The instruments already described in the diborane section can also be used for monitoring work room air for traces of pentaborane [133, 135]. These instruments are more sensitive toward pentaborane than diborane.

Pentaborane and decaborane attack the central nervous system. A small hand-operated monitoring instrument sensitive to 0.4 ppm of pentaborane was developed, and was expected to be useful for detecting leaks or re-checking before re-entry after spillage and cleanup [244]. An electrical instrument that showed great promise was expected to detect concentrations below 0.1 ppm and possibly as low as 0.01 ppm.

One of the electrochemical pentaborane detection instruments was using a membrane electrode in a potentiometric circuitry. A feasibility study was made on the use of a membrane electrode for the detection and measurement of pentaborane in air [245, 246]. A number of plastic films were tested, but none was found to be sufficiently permeable to provide a sensitive and practical sensing device. Instead, a method was proposed to first convert pentaborane to hydrogen, which may then be sensed with the membrane electrode.

A direct reading, automatic and temperature-insensitive instrument for the detection and recording of pentaborane or any other borane in air was sensitive down to and below 0.1 ppm using the flame-emission principle [247]. A small hydrogen flame takes on a typical greenish cast in the presence of boranes, the radiation intensity being proportional to the borane concentration. A multiplier phototube with an appropriate interference filter would detect this colored light and the amplified current at the multiplier anode is sent to an amplifier.

Pentaborane reacts quite differently from diborane or decaborane when it has to be analyzed. It does not form a colored complex with quinoline as decaborane would. It does not hydrolyze as quickly as diborane. It does not react quickly with caustic solutions. Triphenyltetrazolium chloride gives colored products with pentaborane or decaborane. Instead of bubbling air that needs to be analyzed through impingers, pentaborane can be adsorbed on activated charcoal and then desorbed for analysis [248]. Several methods for the analysis of pentaborane vapors in workroom air were described in [180].

### 3.4 Materials of Construction for Pentaborane Equipment

Pentaborane installations can be made from anodized aluminum, brass, copper, lead, or stainless steel. The following non-metallic materials were listed as compatible: dry asbestos, polyethylene, Hycar, Garlock 230, Kel-F, and Teflon. Materials of construction that qualified as acceptable for contact with HEF fuels (alkylboranes) are also acceptable for contact with pentaborane. Very detailed summaries on the design of pentaborane installations are provided in the two reports by Rocketdyne [249, 250] and in some NASA reports [251].

### 3.5 Handling of Pentaborane

There are numerous publications, operating procedures and recommendations for the safe handling of pentaborane at rocket test sites and launch sites [252, 253]. A series of small-scale spill tests for the establishment of safe-distance values for the storage of the propellants was performed using propellant quantities not exceeding 2.5 kg (5 lb<sub>m</sub>) [254, 255]. Propellant quantities used on other large-scale tests conducted in the same test series ranged from 61 to 815 kg (135 to 1800 lb<sub>m</sub>) of total propellant. Similar spill tests were performed with N<sub>2</sub>H<sub>4</sub>, NTO, and ClF<sub>3</sub>. Although pentaborane itself is not shock sensitive, it has been shown that pentaborane can form shock-sensitive mixtures with many solvents commonly found in propellant test areas.

#### 3.5.1 Decontamination of Pentaborane

Pentaborane is soluble without reaction in inert hydrocarbon solvents such as toluene, kerosene, benzene, pentane, or hexane. Water-free kerosene is the standard solvent for washing systems that have been contaminated with pentaborane. Other solvents, especially those containing reactive carbonyl groups and highly halogenated or highly oxygenated solvents, must not be employed for use in pentaborane as they can form shock-sensitive solutions. Solvents of this type, which definitely must not be used, are acetone and other ketones, carbon tetrachloride, and aldehydes.

One method recommended for the decontamination of entire missile systems after use with pentaborane is to flush with a hydrocarbon solvent such as a kerosene to remove most of the material, followed by a flush with a mixture containing 80% methylene chloride and 20% ethyl alcohol and purge dry with gaseous nitrogen [180].

There are counterindications against the use of methylene chloride (dichloromethane) for this purpose: Not only is it quite toxic (causing symptoms similar to CO poisoning) but boranes can react vigorously with halocarbons, [252] specifically lists methylene chloride as a solvent that must be avoided. See also [256].

### 3.5.2 Fire Fighting of Pentaborane Fires

Pentaborane fires can be extinguished with chemical fire retardants [257]. Various phosphate, borate, silicate, and aluminate esters have been tested as extinguishants for pentaborane fires, acting mostly as diluents when mixed with the liquid in the burning puddle [258].

A study on fuels related to pentaborane (HEF compositions) indicated that complexing materials and foams made with inert gases were effective in fighting such fires [259]. This report also noted that hydrogen liberation on hydrolysis of boranes could lead to explosions and fires if oxygen were not excluded from the borane.

A wide range of flame suppressants, mostly halogenated compounds, were tested as inhibitors with an air/pentaborane diffusion flame burner [260]. Methyl iodide was the best material found, and was the only material that put out the flame at the higher pentaborane concentrations. A solution of iodine in carbon tetrachloride also showed some promise as a fire extinguishant. No nitrogen compounds, phosphorus compounds or aqueous solutions were found to be effective. Because pentaborane is not miscible with water and because it has a lower density than water, puddles of pentaborane may float on water and continue to burn.

### 3.5.3 Disposal of Pentaborane

After the termination of the borane-powered B-70 Valkyrie program in 1959, there were ample supplies of pentaborane and other alkylboranes stored and forgotten in some obscure munitions magazines and some cylinders were even buried in a landfill that later became the site for a residential development and then the cylinders needed to be unearthed for proper disposal. There have been two known incidents where people were injured or killed while handling pentaborane and attempting to destroy it [261, 262]. Two onsite treatment methods were identified for decontaminating the cylinders. They included pyrolytic incineration, if the cylinders contained pentaborane, and chemical treatment for decontaminating the empty cylinders. Upon excavating and inspecting the cylinders, all were found to contain only residual quantities of pentaborane, if any. The chemical treatment process was used to decontaminate the cylinders. After controlled venting of any hydrogen gas that may have accumulated in the cylinders, residual pentaborane was dissolved with dilute caustic solution. Methanol was used to rinse the cylinders and then they were flushed with large quantities of water.

Only decades later an enforcement of stricter environmental regulations led to a belated disposal effort for those chemicals inherited from the Cold War period. Some cylinders were disposed of by open pit burning in a remote test area. Various methods for controlled disposal of pentaborane by hydrolysis rather than open pit burning were tested [263, 264]. A pilot plant operation was planned that would use water-alcohol mixtures as the solvolysis reagent. The spontaneous self-ignition of

$B_5H_9$  was quenched by the addition of small concentrations of tetrahydrofuran or 1,2-dimethoxyethane. It was found that the addition of 10 vol.-% of ether provided efficient quenching. When these stabilized solutions were exposed to air, they decomposed and evaporated leaving a residue that was identified by NMR analysis as boric acid. The 90%  $B_5H_9$  + 10% THF solution was safer to handle and its solvolysis reactivity was virtually identical to that of 100%  $B_5H_9$ . Reaction rates were measured by collecting hydrogen evolved during the solvolysis reactions. The data indicated that 50/50 alcohol/water was the optimal solvolysis reagent. This reaction produced a mixture of boric acid and triethoxyborane,  $B(OC_2H_5)_3$ .

### 3.6 Safety Properties of Pentaborane

#### 3.6.1 Flammability Limits of Pentaborane

Stoichiometric mixtures of pentaborane in air would contain 3.37 vol.-%  $B_5H_9$ . The lower limit of flammability is 0.42 vol.-% but an upper limit for pentaborane has never been established because spontaneous ignition of the fuel-air mixture always occurred when attempting to obtain a rich mixture [265]. The flammability limits of pentaborane as a function of the air:fuel ratio and pressure were indicated in Figure 13 in comparison within limits of diborane, hydrogen, and JP-4.

#### 3.6.2 Autoignition of Pentaborane

Pentaborane is pyrophoric and autoignites in air as soon as its partial pressure exceeds 17.3 kPa = 130 mm Hg. Such high concentrations in air would usually be avoided for several reasons, flammability as well as toxicity hazard reasons.

Although this is a book on rocket propellants, information obtained during the examination of pentaborane as a fuel for airbreathing jet engines can be useful for the design of rockets with pentaborane as the fuel as well. The autoignition of pentaborane in a jet engine combustor would be a desirable feature to allow re-ignition after a flame-out or for cruising at high altitudes where the air is very thin [266].

The explosive oxidation and autoignition of pentaborane in air can be inhibited by iron pentacarbonyl vapors [267]. The addition of 1% iron pentacarbonyl suppressed autoxidation altogether. When 0.1% iron pentacarbonyl was added, upper and lower limits of flammability could be determined. This inhibitor raises the autoignition temperature and narrows the range of compositions that can autoignite in air (but it is very toxic and one would not want to prevent pentaborane fires by squirting iron pentacarbonyl all over the place).

At certain conditions of temperature and pressure, pentaborane-oxygen mixtures are spontaneously ignitable and explosive [173]. When oxygen was rapidly added to pentaborane, a first explosion limit region was found at low pressures at room tem-

perature, as well as a glow reaction at mixture pressures below the explosion limit pressures. Pentaborane sprays ignite spontaneously when injected into hot air [268, 269]. The spontaneous ignition limits of air/pentaborane mixtures were determined at 298 K (25 °C) and pressures ranging from 4 to 101 kPa [270]. A flash resulted when air was rapidly admitted to pentaborane vapor. The lean limit of spontaneous ignition in spherical bulbs measuring 6 cm in diameter was approximately 14 vol.-% at 101 kPa and about 55 vol.-% at 10 kPa. The rich limit was not determined, but mixtures containing 75% pentaborane ignited at 6.6 kPa. Stable mixtures of pentaborane and air could not be obtained by the addition of air to pentaborane vapor at 298 K (25 °C) except at pentaborane pressures less than 0.27 kPa. The ignition temperature of pentaborane droplets in air depends on the droplet size [271].

### 3.7 Toxicity of Pentaborane

As pentaborane reacts only slowly with water, it tends to concentrate in fatty tissues and lipids in the body. The primary damage caused by pentaborane poisoning is in the central nervous system.

The results of animal experimentation obtained from inhalation tests showed that pentaborane is more toxic than diborane or hydrogen cyanide. The Section 4 on decaborane contains a table comparing the hazard index of several boranes. Because of its low boiling point, pentaborane must be considered the most toxic of the several boranes.

The American Conference of Governmental and Industrial Hygienists revises and updates TLVs for hazardous chemicals every year. Most recently NIOSH REL has established a TWA for pentaborane of 0.005 ppm (0.01 mg/m<sup>3</sup>) (2005) and an ST of 0.015 ppm (0.03 mg/m<sup>3</sup>). Such a low concentration is difficult to measure with the most common continuous analysis equipment. The olfactory threshold of pentaborane is around 2.5 ppm, and the human nose is thus not a reliable warning instrument. It should be clearly understood that pentaborane concentrations that are detectable by odor are immediately dangerous to life. Additional information on the toxicity of pentaborane can be found in [147–149, 151, 272, 273].

#### 3.7.1 Acute Toxicity of Pentaborane

The LD<sub>50</sub> concentration, which is that concentration at which 50% of the test animals died for a 2-h exposure with pentaborane, was 14.1 ppm for male mice and 19.5 ppm for male rats. These same studies indicated that there may be an accumulative toxic effect build up in the rats with repeated subacute exposures to this compound. Detoxification owing to metabolism did not seem to occur within the animal body when exposed to low concentrations of pentaborane [274].

### 3.7.2 Chronic Toxicity of Pentaborane

In chronic inhalation exposure animal tests with lower subacute concentrations (about 3 ppm) and longer test durations, the effects of pentaborane were very similar to those of decaborane. The symptoms were primarily central nervous system damage and pathological changes in the blood counts [275, 276].

### 3.7.3 Symptoms of Pentaborane Poisoning

Typical symptoms of exposure to dangerous concentrations of pentaborane are nervousness, dizziness, lack of equilibrium, nausea, and frontal lobe headaches. Temporary impairment of higher mental functions, lack of coordination, and transient amnesia for recent events are common. Most frequently, intoxication cases occur from chronic exposure to low concentrations of pentaborane over long periods of time. The symptoms of such exposure are similar to those resulting from lack of sleep, alcoholic hangover, and general physical exhaustion.

Neurological symptoms are the most prominent manifestation of pentaborane poisoning, whereas decaborane produced only performance decrements of reinforced tasks in monkeys as test animals. In addition to CNS disturbance, the boron hydrides also cause cardiovascular effects and damage to both liver and kidney.

The first general symptoms shown are typical in many chemical exposure poisonings. These may include dizziness, blurred vision, nausea, fatigue, and nervousness. The more characteristic symptoms of severe pentaborane exposure are the abnormal muscular contractions or twitching of any part of the body followed by convulsions and then coma.

A lack of vitamin B may aggravate the toxic effects of boranes. Boron hydrides inhibit aspartate aminotransferase and lactic dehydrogenase in the liver, heart, brain, and kidneys of normal rats [277]. Decaborane does not cause a significant loss in activity in the tissues of pyridoxal-deficient rats.

### 3.7.4 Animal Toxicity Test Results with Pentaborane

The various government agencies considering the use of pentaborane and pentaborane derivatives as jet engine fuels and rocket propellants have carried out exhaustive series of animal exposure tests to obtain a better understanding of the toxicity hazard with pentaborane, to establish safe threshold levels for the work place, and to eventually develop better first aid post-accident treatment methods in the case of accidental poisonings in humans. They were also looking for preventive medications to be administered to personnel working in high-risk areas.

In animal tests with rats exposed 5 h/day to 3.3 ppm pentaborane the mortality was very high after only a few days of testing.

The acute LC<sub>50</sub> with rats exposed for 5 min was 66.6 ppm, after 15 min it was 31.2 ppm, after 30 min it was 15.2 ppm and after 1 h it was 10.4 ppm [278, 279]. The LC<sub>50</sub> concentrations for mice exposed for the same durations were 40.5, 18.6, 10.6, and

7.8 ppm respectively. Single exposures of dogs for 5-, 15-, and 60-min periods to 26, 12, and 3 ppm pentaborane vapor respectively produced borderline signs of toxicity [280]. Daily repeated exposures at approximately these levels caused convulsions, apprehensiveness, scleral injection, and miosis after the second exposure. Single exposures at 9.3, 5.0, and 1.4 ppm for 5-, 15-, and 60-min periods produced no detectable effects with the techniques employed. However, repeated daily exposure for 5 days to these levels caused irritability, miosis, and increased response time in a conditioned avoidance response test. Dogs exposed cutaneously for single 2-, 4-, and 6-h periods to 580, 550, and 710 ppm of  $B_5H_9$  respectively showed minimal or no signs of toxicity [281, 282].

In another test series the LC50 after 2 h of exposure was 14.1 ppm (0.037 mg/L) with male mice and 19.5 ppm (0.051 mg/L) with rats [283]. In similar tests where the animals were exposed for 4 h instead of 2 h, the LC50 was 10.9 ppm (0.028 mg/L) with male mice and 17.8 ppm (0.046 mg/L) with rats. The surviving animals recovered faster following a pentaborane poisoning episode than a decaborane poisoning episode.

In another test series with rats the LC50 after a 2-h exposure was reported to be 17 ppm [152]. The olfactory threshold in that source was listed as 2.5 ppm.

Median lethal doses of pentaborane-9 by intraperitoneal (*i.p.*) and inhalation administration to rats were determined to be 3.7 and 0.42 mg/kg respectively [284]. The intravenous (*i.v.*) median lethal dose to the rabbit was 0.52 mg/kg. The suggestion was made that pentaborane-9 might not oxidize appreciably prior to inhalation, and was almost quantitatively removed from respired air after passing through the lungs. Table 14 is a summary of acute toxicity data of pentaborane that were used by NIOSH to establish IDLH limits.

**Table 14:** Acute toxicity data summary for pentaborane.

| Species | LC50 (ppm) | Time   | Adjusted 0.5-h LC (CF) | Derived value | References |
|---------|------------|--------|------------------------|---------------|------------|
| Mouse   | 3          | 4 h    | 6 ppm (2.0)            | 0.6 ppm       | [285]      |
| Rat     | 6          | 4 h    | 12 ppm (2.0)           | 2 ppm         | [151]      |
| Mouse   | 3.4        | 4 h    | 6.8 ppm (2.0)          | 0.7 ppm       | [151]      |
| Dog     | 35         | 15 min | 28 ppm (0.79)          | 2.8 ppm       | [286]      |
| Monkey  | 244        | 2 min  | 100 ppm (0.41)         | 10 ppm        | [286]      |
| Rat     | 67         | 5 min  | 37 ppm (0.55)          | 3.7 ppm       | [280]      |
| Mouse   | 40         | 5 min  | 22 ppm (0.55)          | 2.2 ppm       | [280]      |
| Rat     | 31         | 15 min | 24 ppm (0.79)          | 2.4 ppm       | [280]      |
| Mouse   | 19         | 15 min | 15 ppm (0.79)          | 1.5 ppm       | [280]      |
| Rat     | 15         | 30 min | 15 ppm (10)            | 1.5 ppm       | [280]      |
| Mouse   | 11         | 30 min | 11 ppm (10)            | 1.1 ppm       | [280]      |
| Rat     | 10         | 1 h    | 13 ppm (1.25)          | 1.3 ppm       | [280]      |
| Mouse   | 6          | 1 h    | 7.5 ppm (125)          | 0.8 ppm       | [280]      |

### 3.7.5 Central Nervous System Effects of Pentaborane in Test Animals

Investigations of the influence of decaborane and pentaborane on biogenic amine metabolism were undertaken to assist in the elucidation of the toxic mechanisms and sites of action of boron hydrides in animals [288]. Brain and heart tissue serotonin and norepinephrine were found to be significantly depleted after treatment of test subjects with the boron hydrides. The testing of a number of potential antidotes for the treatment of the toxic symptoms and biogenic amine changes due to exposures to boron hydrides has resulted in the discovery of several new antidotal drugs for the toxic effects of decaborane. Some of the pentaborane effects were reversed following a norepinephrine infusion [289, 290].

Adverse cardiac and neurological symptoms were produced in animals following doses of decaborane(14) and pentaborane(9) [291]. Serotonin in adult rat brains was increased slightly at 4, 6, 8, and 12 h whereas norepinephrine was markedly lowered after 20 mg/kg IP of decaborane. A dose of 2.5 mg/kg IP of liquid pentaborane-9 lowered norepinephrine nearly 100% at 2 h, elevating serotonin 80%. Sedation and decreases in brain norepinephrine at 16 and 24 h after decaborane intoxication can be prevented by simultaneous or prior administration of 50 mg/kg IP of pargyline hydrochloride (*N*-methyl-*N*-benzyl-2-propynylamine hydrochloride). Similar treatments with 100 mg/kg IP of iproniazid phosphate did not block the fall in tissue norepinephrine due to decaborane.

### 3.7.6 Effects of Pentaborane on Metabolism of Test Animals

In a study of the fate of pentaborane-9, evenly labeled with tritium, in small animals, rats given B<sub>5</sub>H<sub>9</sub> by *i.p.* injection evolved 36–37% of the tritium label as molecular hydrogen over a 2- to 3-h period [292]. A non-volatile hydrolysis intermediate rapidly formed in the bloodstream concurrently as molecular hydrogen was evolved by treated animals. Tritium in the hydrolysis intermediate was found to be non-exchangeable into water. However, the hydrolysis intermediate slowly disappeared and approximately an equivalent amount of tritium could be detected in the body water of treated animals. A study of the effect of pentaborane-9 intoxication upon glucose catabolism by rats showed that total respiratory CO<sub>2</sub> production by intoxicated rats was slightly greater than that of normal rats. Catabolism of glucose via the glycolytic pathway appeared to be inhibited during the initial 4 h after B<sub>5</sub>H<sub>9</sub> administration by *i.p.* injection. Pentaborane-9 intoxication appeared to affect glucose catabolism for only a 6- to 8-h period.

### 3.7.7 Central Nervous System Damage in Persons Exposed to Pentaborane

Neuropsychological tests were administered to 14 workers and rescue squad personnel approximately 2 months following an accidental exposure to pentaborane [293]. Performance decrements were evident on 5 of 11 neuropsychological tests, including measures of sustained attention and recent memory. These results indicated mild residual brain dysfunction following pentaborane intoxication, including possible dysfunc-

tion in subcortical regions mediating memory processes and in cortical areas mediating visuo-spatial abilities.

Fourteen individuals briefly exposed accidentally to pentaborane by inhalation were evaluated for neuropsychiatric abnormalities 4–12 weeks after exposure [294]. Results of physical, neurological, and routine laboratory evaluations were normal. Initial and persistent psychiatric symptoms, neuropsychological deficits, electroencephalographic changes, elevated central nervous system neurotransmitter levels, and ventricular brain ratios (computed tomographic scan) provided evidence for central nervous system damage. Seven patients met the diagnostic criteria of the Diagnostic and Statistical Manual of Mental Disorders, Ed. 3, for post-traumatic stress disorder, and seven patients had neuropsychological test evidence for mild brain dysfunction. Patients suffered a combination of organic brain insult and psychological trauma. These results contradict previous literature that claimed that most symptoms resolved within the first week after exposure to pentaborane.

Pentaborane poisonings are unique with respect to the rapid and devastating neurologic consequences. Three cases of pentaborane poisoning resulting from accidental exposure were characterized by the rapid onset of seizures and spasms accompanied by severe metabolic acidosis without respiratory compensation [295]. Serum transaminase levels were elevated and liver damage was demonstrated histologically. One patient died and another sustained severe neurologic damage.

Fourteen individuals who had been briefly accidentally exposed to pentaborane were reevaluated for a period of 18 months following an initial neuropsychiatric study [296]. Psychiatric interviews utilizing standardized diagnostic criteria, neuropsychological and psychological assessment, and CT scan ventricular brain ratios were reevaluated and revealed worsening psychological factors. Post-traumatic stress disorder, major affective disorder, alcohol abuse and phobias were the most common diagnoses at follow-up.

### **3.7.8 Epidemiological Studies with Pentaborane Worker Cohorts**

During the period 1950–1962 a large quantity of pentaborane was produced by Callery Chemical Company without any serious poisoning accidents.

Psychodiagnostic testing was administered to personnel with a work history on a pentaborane project [297]. The tests consisted of questions referring to neuropsychiatric and psychosomatic symptoms, the results of which were related to job adjustment as measured by several criteria. Although the analysis of findings did not reveal statistically significant relationships, there was some evidence suggestive of the practical usefulness of such tests. Information obtained from these psychological measuring tools can serve a purpose as part of the personal medical history to assist physicians in diagnosing complaints of propellant intoxication, the symptomatology of which is often not clear.

During a thorough medical examination of 60 workers who were exposed to various subacute concentrations of pentaborane below the sensitivity threshold of moni-

toring equipment, 31 workers were found to have slight symptoms of pentaborane poisoning but without any pentaborane being detectable in their post-work shift blood samples. Even after one year of employment in the plant there were no pathological clinical changes in lung, liver, or kidney function [298]. A clinical evaluation of all of the exposed workers at the end of a year's production revealed no observable effects. The protective gear worn provided good, though not complete, protection. Further study of the hazards of the boranes will require a monitoring instrument of better sensitivity to evaluate the acute poisonings and the protective gear worn.

Extensive animal experiments, as well as limited observation upon humans, indicated that boron hydrides possess an unusual degree of toxicity. Intoxication may occur from inhalation, ingestion or skin absorption. Medical tests were performed on 154 technical personnel who had worked in a borane production plant for 3 years [299]. In order to maintain safe working conditions, the pentaborane concentration in the air should not exceed 5 parts per billion (by volume), but that is below the sensitivity of most analytical instruments.

It would have been very useful to have a clinical test to measure boron concentration in blood, skin wipes or urine of workers before and after each work shift, but instrumentation available at that time did not have the necessary sensitivity [300].

### 3.7.9 Maximum Allowable Pentaborane Concentrations

A very useful occupational health guideline for exposure of workers to pentaborane was published by CDC-NIOSH in 1978 [301]. As of May 1994, the NIOSH REL was 0.005 ppm (0.01 mg/m<sup>3</sup>) and the short-term exposure limit (STEL) was 0.015 ppm (0.03 mg/m<sup>3</sup>). The 1994 OSHA PEL was 0.005 ppm (0.01 mg/m<sup>3</sup>), unchanged from an earlier (1989) recommendation of 0.005 ppm (0.01 mg/m<sup>3</sup>) TWA, 0.015 ppm (0.03 mg/m<sup>3</sup>) STEL. The 1993–1994 ACGIH TLV recommendation was 0.005 ppm (0.013 mg/m<sup>3</sup>) TWA, and 0.015 ppm (0.039 mg/m<sup>3</sup>) STEL. The basis for the original (Standards Completion Program) IDLH of 3 ppm was the mouse 4-h LC50 of 3 ppm reported by Jacobson in 1958 [285] and cited by ACGIH in 1971. The IDLH was later revised to 1 ppm based on acute inhalation toxicity data in animals reported by Jacobson 1958 [285], Levinskis et al. 1958 [151], and Weir et al. 1964 [280].

The tentative emergency exposure limits for pentaborane vapor established in 1966 are listed in Table 15, but those limits are probably outdated and require re-examination in view of the extreme toxicity of this chemical:

**Table 15:** Emergency exposure limits for pentaborane vapor.

| Exposure duration, min | Emergency exposure limit, ppm |
|------------------------|-------------------------------|
| 5                      | 25                            |
| 15                     | 8                             |
| 30                     | 4                             |
| 60                     | 2                             |

Data source: [302].

## 4 Decaborane(14)

Decaborane(14),  $B_{10}H_{14}$ , CAS RN [17702-41-9], is a colorless, crystalline solid that melts at 372.8 K (99.7 °C) and sublimes readily. It dissolves in all organic solvents and in pentaborane.

### 4.1 Preparation of Decaborane

Decaborane(14) is formed along with other higher boron hydrides when diborane or pentaborane is heated to above 393 K (120 °C) [303]. The mixture of solid products formed by pyrolysis of diborane is usually extracted with saturated hydrocarbon solvents, which dissolve the decaborane, but not the higher boranes. The dissolved decaborane can be precipitated by reaction with a secondary alkyl amine [304]. It is difficult to control the diborane pyrolysis process so as to optimize the yields of pentaborane and decaborane and minimize the wasteful formation of insoluble high-molecular mass boranes [177]. A more selective laboratory procedure for the preparation of decaborane(14) consisted of three distinct steps [305, 306]:

- (1) Conversion of  $B_5H_9$  to  $[N(CH_3)_4]B_9H_{14}$  by reacting a 2:1 molar ratio of  $B_5H_9$  with NaH in THF in the presence of  $[N(CH_3)_4]Cl$  at room temperature.
- (2) Removal of THF and addition of  $BCl_3$  and reaction at 284 K (11 °C).
- (3) Sublimation of  $B_{10}H_{14}$  at 284 K (11 °C) from the solid reaction mixture.

A process for the preparation of decaborane that appears suitable for adoption by large-scale plant production involved the pyrolysis of diborane at constant temperature and pressure, using a closed recycle system with continuous diborane feed and decaborane withdrawal [303]. Optimal reaction occurred with a reactor residence time of 4 to 6 s, and temperatures of 453 to 458 K (180 to 185 °C), using diborane in concentrations of 30 to 40 mol-% at pressures of 170 to 180 kPa (10 to 11 psig). Diborane conversions of 80 to 90% and decaborane-corrected yields of 50 to 60% were attained, with a material accountability of 90%.

The synthesis of n-hexylcarborane, a burning rate modifier for improved solid propellants, depends on the availability of decaborane-14, a material that is not commercially available in large quantities. Laser-induced chemistry (LIC) can synthesize decaborane-14 from diborane in high yields and high purity using both  $CO_2$  and DF laser frequencies [307–309]. The products are decaborane-14 formed as white crystals and pentaborane-9 in the vapor state; the two are easy to separate. No polymer (which is an unwanted byproduct that is always present in thermal pyrolysis) was observed when the laser power was kept below a certain threshold (10 W/cm<sup>2</sup> for the  $CO_2$  laser). Also, the  $B_5H_{11}$  byproduct is always present in pyrolysis yet never observed in LIC synthesis.

## 4.2 Physical Properties of Decaborane

Some of the physical properties of decaborane are summarized in Table 16. Vapor pressure data are listed in Table 17.

**Table 16:** Physical properties of decaborane.

|                                    | SI units               | Other units     | References |
|------------------------------------|------------------------|-----------------|------------|

Data source: [310]

The vapor pressure of decaborane between 315 and 395 K can be represented by the equation [311]:

$$\log_{10} p = -\frac{4225.345}{T} - 0.0107975T + 16.63911,$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

### 4.2.1 Optical Properties of Decaborane

The IR spectrum of decaborane shows two bands, one at 5205 and the other at 7505 cm<sup>-1</sup>. These bands correspond to the two bands of pentaborane assigned to the first and second overtones of a B—H stretching frequency [73].

### 4.2.2 Thermodynamic Properties of Decaborane

Thermodynamic properties of decaborane are summarized in Table 18

**Table 18:** Thermodynamic properties of decaborane.

|                                    | SI units                                   | Other units                                  | References |

### 4.2.3 Molecular Structure of Decaborane

Decaborane(14) crystallizes in disordered orthorhombic crystals, space group *Pnnm*,  $a = 7.225 \text{ \AA}$ ,  $b = 10.44 \text{ \AA}$ ,  $c = 5.68 \text{ \AA}$  [312, 313]. The molecular structure of decaborane resembles that of a basket (Figure 22).

**Figure 22:** Molecular structure of decaborane(14).

When assembling a 3-D structure of decaborane with any of the chemical structure illustration programs, it is very difficult to get a clear view of the internal structure of decaborane. Regardless of how one rotates the molecule in any of the *x*-, *y*-, or *z*-axes to

obtain a different aspect, several atoms in the rear of the molecule are always occluded and out of view (Figure 23). It would be best to display this molecule as a .gif image and allow it to slowly rotate. The occlusion is even more hindering if the van der Waals radii of the atoms are displayed.

**Figure 23:** Molecular structure of decaborane(14).

### 4.3 Chemical Properties of Decaborane

A detailed review of the chemistry of decaborane [314] contains sections on the structure and reactivity of decaborane, pyrolysis, hydrolysis, alcoholysis, and thiolysis of decaborane, decaborane as an acid, nucleophilic substitution in decaborane, electrophilic substitutions, and the stable anion  $B_{10}H_{10}^{2-}$ . See also [315].

#### 4.3.1 Reactions of Decaborane

Decaborane is a strong acid in dimethylformamide as the solvent and forms salts with alkali metals, such as  $B_{10}H_{13}Na$  [316]. The  $B_{10}H_{10}^{2-}$  anion in  $B_{10}H_{10}[N(CH_3)_4]_2$  is quite stable [317].

The hydrolysis of decaborane takes place even more slowly than that of pentaborane. Likewise, the rate of autoxidation is much slower than that of pentaborane.

Decaborane forms adducts with Lewis bases, typical electron donors [318]. The best characterized adducts are those with aliphatic amines, but similar products are obtained with aromatic amines [319].

The adduct of decaborane with ammonia contains two moles of ammonia per mole of decaborane. The formation of the adduct is reversible [320]. Adducts of decaborane with one, two or three moles of diethylamine have been characterized by XRD [321]. These solid adducts release decaborane on treatment with acid. The reactions of decaborane with secondary or tertiary amines, forming Lewis adducts, can be used for the separation of decaborane from reaction mixtures during the production of decaborane [304].

Solutions of a hydrazinium decaboranate in hydrazine were patented as rocket fuels [322, 323]. This salt is soluble in hydrazine and can be prepared by a reaction

of diammonium decaboranate with hydrazine. Similar salts are formed by reaction of hydrazine or alkylhydrazines with undecaborane(14) [324].

Decaborane reacts with acetonitrile to form an adduct  $B_{10}H_{14} \bullet (H_3CCN)_2$ . Similar adducts are formed by reaction of alkyl decaboranes with dinitriles [325]. The reaction is believed to involve one mole of decaborane (alkyl decaborane) and two moles of the dinitrile, leading to a viscous, polymeric material with a putty-like consistency.

#### 4.3.2 Thermal Stability of Decaborane

Decaborane is quite stable and can be stored at room temperature indefinitely. The decomposition of decaborane starts only at temperatures above 473 K (200 °C) [326]. Differential thermal analysis curves of decaborane heated in air showed a slight exotherm up to 367 K (94 °C); then it began an endotherm due to melting at 373 K (100 °C). After melting, the curve returned to the base line and remained there from 378 to 398 K (105 to 125 °C). At 398 K (125 °C) it began to decompose and decomposition continued up to 433 K (160 °C). In helium only an endotherm due to melting was observed at 373 K (100 °C). No evidence of decomposition was to be seen up to 423 K (150 °C). On cooling, the freezing occurred at 361 K (88 °C), indicating supercooling. See also [327–330].

The thermal stability of decaborane was investigated at temperatures of 475 and 525 K (202 and 252 °C) [331]. The products of decomposition were hydrogen and a boron hydride, which is a solid or viscous liquid. The following equation was developed from which may be calculated the time required to decompose 20% of decaborane at any other temperature:

$$\log(t_{20\%} - 2) = 8.6 \times \frac{10^3}{T} - 16.0,$$

where  $T$  is temperature in kelvin and  $t$  is the time for decomposition of 20% of decaborane in minutes.

Rate constants for the homogeneous first-order disappearance of decaborane during vapor phase pyrolysis were measured over the range 443–511 K (170–238 °C), and an activation energy of 173 kJ/mol (41.4 kcal/mol) was calculated [332]. Inhibition by hydrogen, but not by other gases was demonstrated. Comparison of the rates for H-decaborane and deuterodecaborane indicated that the rupture of B–H or B–D bonds was rate determining. Decaborane disappeared by a rapid polymerization reaction without immediate loss of hydrogen to form an intermediate polymer consisting of decaborane-like units, followed by further loss of hydrogen and molecular weight increase with cross-linking to form non-volatile solid hydrides. No interim reactants more volatile than decaborane were observed. Hydrogen was found to split out preferentially at the external B–H bonds initially, rather than at the bridged hydrogen positions.

Premature decomposition of decaborane limits the yield during production of decaborane by pyrolysis of diborane. The kinetics of the pyrolysis of decaborane were

investigated in a static system within the temperature range 483–523 K (210–250 °C) and at decaborane pressures of 8–80 kPa (60–600 mm Hg) [333]. The decomposition led to non-volatile solid hydrides and hydrogen. Experiments were carried out in a sealed vessel for varying times at 483, 503, and 523 K (210, 230, and 250 °C) and initial decaborane pressures of 8, 16, 40, and 80 kPa (60, 120, 300, and 600 mm Hg). For experiments on retardation by hydrogen, a known pressure of hydrogen was admitted before sealing. The decomposition reaction was of first order with respect to decaborane, slightly retarded by hydrogen. The activation energy was  $174 \pm 2$  kJ/mol ( $41.6 \pm 0.5$  kcal/mol). Above 60% conversion, the reaction tended to be of greater than first order. Hydrogen was also formed by decomposition of the non-volatile solid hydrides, and its rate of formation in this way was strongly retarded by hydrogen. One of the objectives of the work was to see if the decomposition of decaborane was to blame for the formation of non-volatile (useless) solid hydrides during the pyrolysis of diborane at 513 K (240 °C). It was shown that at 513 K (240 °C), with 1:5 diborane:hydrogen ratio and a total flow rate of 0.4 l/min, only about 0.1% of decaborane was converted by thermal decomposition alone into non-volatile solid hydrides.

Even a long time after the excitement of boranes as jet engine and rocket fuels has subsided, pyrolysis of decaborane is still being used for boriding metal surfaces, deposition of boron thin films, doping semiconductors, and the production of nano-sized boron particles.

### 4.3.3 Analysis of Decaborane

The quantitative analysis of decaborane in solutions of inert solvents can be achieved by volumetric titration [326]. This method for the quantitative determination of decaborane performs an oxidation of the sample in glacial acetic acid with excess potassium iodate, reaction of excess iodate with potassium iodide, and titration of the liberated iodine with sodium thiosulfate.

Decaborane can be analyzed by reaction with potassium hexacyanoferrate(III) [334]. The reduction of hexacyanoferrate(III) by boranes forms hexacyanoferrate(II) and Prussian Blue, which can then be analyzed colorimetrically. Another method uses the reduction of phosphomolybdic acid to the blue dye. These reductions are not specific to decaborane or any borane.

An alkaline solution of triphenyl tetrazolium chloride can be reduced by boranes (pentaborane or decaborane) to form an insoluble red formazan, which can then be extracted with xylene and analyzed colorimetrically [335].

Nine methods for the determination of decaborane were evaluated by analyzing commercial samples ranging from 90 to 97% pure [336]. Gas chromatographic, IR, UV, and iodine redox volumetric procedures gave comparable results at the 95% confidence level. Decaborane was determined by five methods without significant interference by the impurities present. An alkaline titration method gave high results because of the acidic impurities. A 3-naphthoquinoline [benzo(f)quinoline] colorimetric method gave comparatively low results. Mole percent purity can be determined by

a freezing point depression method. The iodine titration method was recommended as a standard when high-purity decaborane is unavailable for calibration of other methods.

The  $\beta$ -naphthoquinone spectrophotometric method had a sensitivity of 0.1  $\mu\text{g}$  of decaborane/mL [337]. Another colorimetric reagent with even better sensitivity for the analysis of decaborane is 1,2-bis(4-dipyridyl)ethylene [338].

#### 4.4 Toxicity of Decaborane

Based on the quantity of borane absorbed into the body, decaborane is the most toxic of all boranes. The hazard in the handling of boranes, however, is determined not only by their toxicity as measured by LC50 or LD50, but also by their vapor pressure. Fortunately, the vapor pressure of decaborane at room temperature is very low, such that the quotient of vapor pressure divided by the LD50 or LC50 (also called the hazard index) is not the worst in the list examples shown in Table 19. The hazard index is a better measure for risk and hazards in handling than the LC50 or LD50.

**Table 19:** Hazard index of boranes and other chemicals.

| Compound           | Gross formula                  | Hazard index |
|--------------------|--------------------------------|--------------|
| Pentaborane        | $\text{B}_5\text{H}_9$         | 40300        |
| Diborane           | $\text{B}_2\text{H}_6$         | 25000        |
| Hydrazine          | $\text{N}_2\text{H}_4$         | 33           |
| Alkylborane        | $\text{B}_x\text{H}_y\text{R}$ | 11.5         |
| Benzene            | $\text{C}_6\text{H}_6$         | 7.8          |
| Tetrachloromethane | $\text{CCl}_4$                 | 6            |
| Decaborane         | $\text{B}_{10}\text{H}_{14}$   | 1.4          |

A review of literature data showed no cases of human accidental exposure to decaborane alone, but that was prior to the expansion of borane fuel production [147]. Most of the information that is available and discussed in the following paragraphs is based largely on animal experimentation. The mode of action of decaborane within the body is not quite understood. Available data indicated that it behaves somewhat like pentaborane, but to a lesser degree, in its toxicological effects. In general, toxicity studies show that recovery from pentaborane exposure is more rapid than from decaborane poisoning. Primary effects of decaborane exposure are disturbances of the central nervous system. Prolonged exposure may cause liver and kidney damage. Some animal exposure tests revealed corneal damage, hemorrhagic adrenal glands, and cardiovascular disturbances. A cumulative toxic effect may be exhibited by animals with repeated small exposures to decaborane. Detoxification of absorbed decaborane did not occur within the animal body. There is no quantitative information on

the cumulative or detoxifying action of decaborane in humans. Symptoms exhibited by animals exposed to decaborane may be compared with those exhibited by animals exposed to pentaborane (muscular incoordination, convulsions, and coma). Decaborane depleted the hepatic glycogen content in rats [339].

#### 4.4.1 Acute and Chronic Toxicity of Decaborane

In toxicity tests with intraperitoneal administration of decaborane the LD<sub>50</sub> was 33 mg/kg with mice and 23 to 28 mg/kg with rats [152]. When decaborane was administered to rats by way of stomach tube, the LD<sub>50</sub> was 64 mg/kg. Decaborane that was dissolved in oil and applied cutaneously to the skin of rabbits or rats resulted in an LD<sub>50</sub> of 113 mg/kg for rabbits and 640 mg/kg for rats, based on a 24-h exposure. The LC<sub>50</sub> for a 4-h exposure of mice to decaborane vapors was 26 ppm, based on a 48-h post-exposure observation period. The rate of survival of rats was higher than that of mice, but surviving animals exhibited greater irritability. The animals recovered more slowly after a decaborane poisoning than after a pentaborane poisoning.

In another test series, the acute toxicity LC<sub>50</sub> after a 4-h inhalation exposure period with mice was 36.5 ppm (0.182 mg/L) and 25.7 ppm (0.122 mg/L) after a 24- to 28-h inhalation period [283]. In a parallel test under identical conditions, all rats survived such that an LC<sub>50</sub> could not be determined. Exposure of test animals to subacute concentrations of 20 ppm caused rapid weight loss, disorders of the central nervous system, opacification of the cornea, nausea, and spasms with deadly consequences. The mammal metabolism does not appear to have a mechanism for the digestion of the poison, such that even small concentrations accumulated to toxic quantities over the course of time [275]. See also [244, 340–343]. The acute toxicity data in Table 20 were used by NIOSH in selecting a threshold for IDLH [344]. See also [345].

**Table 20:** Decaborane lethal concentration data.

| Species | LC <sub>50</sub>      | Time | Adjusted 0.5-h LC (CF)      | Derived value        | References |
|---------|-----------------------|------|-----------------------------|----------------------|------------|
| Rat     | 276 mg/m <sup>3</sup> | 4h   | 552 mg/m <sup>3</sup> (2.0) | 55 mg/m <sup>3</sup> | [244]      |
| Mouse   | 72 mg/m <sup>3</sup>  | 4 h  | 144 mg/m <sup>3</sup> (2.0) | 14 mg/m <sup>3</sup> | [244]      |
| Mouse   | 144 mg/m <sup>3</sup> | 4 h  | 288 mg/m <sup>3</sup> (2.0) | 29 mg/m <sup>3</sup> | [340, 341] |

Data source: [344]

#### 4.4.2 Central Nervous System Effects of Decaborane

Central nervous system damage due to inhalation or other absorption of decaborane is more pronounced and longer lasting for decaborane than for the other boranes [346, 347].

One single *i.p.* injection of 5 mg/kg decaborane in monkeys produced a marked behavioral depression, with only moderate electroencephalographic modifications, followed by death in 18 h [348]. Four daily doses of 3 mg/kg produced depression, som-

nolence, twitching in both arms, accompanied by bursts of high-voltage activity, localized in the internal capsule. Death occurred 3 days later. Daily doses of 1 mg/kg up to a total of 14 mg/kg produced depression, muscular twitching, anorexia, and a typical electroencephalographic pattern, but the animals recovered completely.

Ten adult monkeys were injected with either 1, 2 or 4 mg/kg of decaborane, and their performance on various operant tasks was compared with baseline performance [349, 350]. All animals exhibited a performance decrement on at least one task, with six of the subjects exhibiting a decrement on the remaining tasks. In over half the cases performance changes preceded clinical symptoms. There was no significant difference between the 2 and 4 mg/kg exposures. Subjects exposed to levels of decaborane such as those employed in this research may be expected to exhibit a performance decrement or clinical symptoms during the first 50 h. See also [351].

#### 4.4.3 Cardiovascular Effects of Decaborane

Decaborane (4–10 mg/kg, *i.v.*) produced bradycardia and an initial transient hypertensive effect in the anesthetized dog [352]. Decaborane caused an immediate decrease in cardiac output without affecting stroke volume, whereas right ventricular contractile force gradually decreased to below basal levels in approximately 60 min. The bradycardia produced by decaborane was partially antagonized in the initial stages by atropine and chlorisondamine. Subsequently, these agents had no effect on this response of decaborane. It was concluded that the initial hypertensive effect and increase in perfusion pressure were due to the acute release of norepinephrine from peripheral adrenergic neurons and the myocardial depression was induced by cholinergic stimulation as well as by a direct, non-specific depression of myocardial contraction induced by decaborane. See also [353].

#### 4.4.4 Enzyme Effects of Decaborane

Intermediates of decaborane hydrolysis inhibit glutamic-oxaloacetic transaminase (GOT) [354]. The inhibition of transaminase activity is kinetically irreversible when the ratio of apoenzyme to pyridoxal phosphate is kept constant, but is partially reversed when excess pyridoxal phosphate is added. The GOT-inhibitory activity disappeared when the intermediate was neutralized by pyridoxal phosphate. Prior loading of mice with pyridoxine raised the LD<sub>50</sub> of decaborane. It was postulated that toxicity of decaborane attendant upon inhibition of pyridoxal phosphate requiring enzymes is due not to decaborane per se, but to reduction of pyridoxal phosphate by a substance formed non-enzymically from decaborane in the presence of water.

Decaborane and carboranes inhibited hepatic microsomal enzymes isolated from adult male rats, ethylmorphine *N*-demethylase and aniline hydroxylase *in vitro* [355]. Pyridoxal phosphate, a coenzyme that alters the inhibitory actions of decaborane on certain enzyme systems, had no effect on the interaction of decaborane with these microsomal systems. Both decaborane and the carboranes are bound to cytochrome

P-450. The activity of some microsomal systems was unaltered after a single dose (12 mg/kg) of decaborane. During these studies morphologic changes of liver tissue occurred, confirming previous studies by other investigators that the liver is a site of pathology caused by decaborane.

#### 4.4.5 Accidental Exposures to Borane Fuels

A number of accidental exposures of personnel to borane fuels were described in Schoettlin et al. [149]. Here are some examples.

A rocket development company was conducting routine pentaborane firings. One research engineer working in the area wore no protective mask or equipment. At 3:30 PM he felt nervous. After this he had a lapse of memory. After arriving at work on the following morning, it was noted that he was sweating profusely and was very confused. He spoke slowly because of an inability to think, and was unable to describe what was wrong. He had a wide-awake stare and recent memory loss. Upon questioning, he complained of aching in all of his muscles. It was observed that when he was touched he developed muscle tremors. He complained of having not slept the previous night. He noted, on attempting to walk, that his "knees felt stiff, and back and hips felt as though they were slipping backwards." Oxygen therapy was started. At one time during observation he developed tetany and opisthotonos.

At another test site, a group of chemists were investigating the properties of high-energy fuels. Within 2 months of commencing this research, they admitted that minute amounts of the fuel had been spilled onto the chemist's hands and vapor had been inhaled. The chemists exposed to this developed frequent headaches in the frontal and occipital regions. These headaches persisted for 1 to 2 h.

A flight surgeon was conducting a series of electroencephalograms (EEG) on pilots to determine central nervous system damage from in-flight accidental inhalation of fuel fumes. Obvious abnormalities were observed on the EEG tracings made on the pilots.

A group of 119 rocket fuel handlers doing routine work and not involved in recent borane accidents and 22 controls were followed over time using serial electroencephalograms. Although observable, clinically important EEG changes were noted, the number of cases showing changes attributable to boranes was small. The pattern of central nervous system damage reconstructed from these few cases was as follows:

1. Known normals may convert to abnormal after exposure.
2. Not all normals may convert to abnormal after the initial exposure, but may do so after repeated exposure.
3. Post-exposure abnormalities tend to revert to normal about 1 year after exposure.

The EEG tracings showing post-exposure changes exhibited only slow activity in either or both the resting and hyperventilation records.

#### 4.4.6 Therapy of Decaborane Poisoning

Tests on therapy of decaborane poisonings in laboratory animals showed that the mortality can be substantially reduced by simultaneous administration of atrolactamide/sodium lactate 1:500 or methylene blue [356]. Themisone, also known as atrolactamide or M-144, was found in the 1950s to be a very potent anticonvulsant. Acute decaborane poisonings in animals have been treated with methocarbamol (Robaxin) or barbiturates. The survival rate of rabbits exposed to decaborane was improved by immediate administration of methylene blue [357, 358].

Rats were injected *i.p.* with decaborane and observed over a 7-day period to determine their toxic reactions, including death rate [359]. Pyridoxine, pyridoxal, and pargyline were tested in the decaborane-treated rats as antidotes for the observed manifestations of the boron hydride injection. In these studies pyridoxine (1 mmol/kg) given simultaneously with decaborane prevented the convulsions and hyperactivity usually seen in rats treated with decaborane alone (20 mg/kg) and caused a significant decrease in the number of deaths.

If decaborane comes into contact with skin, the contaminated areas should be washed first with a 1% solution of triethanolamine, followed by washing with soap and water.

#### 4.4.7 Maximum Allowable Concentrations of Decaborane in Workroom Air

The maximum allowable concentration of decaborane in workroom air established by the ACGIH in the 1993–1994 TLV is 0.25 mg/m<sup>3</sup> (0.05 ppm) TWA. Other recommended limits are NIOSH REL: 0.3 mg/m<sup>3</sup> (0.05 ppm) TWA, NIOSH STEL 0.9 mg/m<sup>3</sup> (0.15 ppm) [skin]; OSHA PEL: 0.3 mg/m<sup>3</sup> (0.05 ppm) TWA [skin]; 1989 OSHA PEL: 0.3 mg/m<sup>3</sup> (0.05 ppm) TWA, OSHA STEL 0.9 mg/m<sup>3</sup> (0.15 ppm) [skin]. The IDLH threshold was estimated at 100 mg/m<sup>3</sup>. The IDLH was based on the review by International Labour Office (1971) that the 4-h LC50 was 122 to 230 mg/m<sup>3</sup> for small animals [163, 164]. The olfactory threshold for decaborane is 0.3 mg/m<sup>3</sup> (for comparison: diborane 2 to 4 mg/m<sup>3</sup>; pentaborane 2.5 mg/m<sup>3</sup>).

#### 4.4.8 Protective Equipment

Gas masks containing a silica gel filter are effective in retaining decaborane vapors, but the filter capacity may be exhausted after only a few hours [360]. Activated charcoal filters are only half as effective as silica gel filters. Granulated soda lime or triethanolamine soaked into porous porcelain are usable only for short times. Gas mask filters containing combinations of these materials may be effective against decaborane and other boranes.

## 5 Complex Boron Hydrides

Complex boron hydrides can be formed with ionic or covalent bonds. Many complex boron hydrides have been evaluated as rocket propellants and gas generant constituents. Others were examined as potential hydrogen storage media [361].

### 5.1 Ionic Boron Hydrides

Salts containing the  $\text{BH}_4^-$  anion are called complex borohydrides, or, more specifically, tetrahydroborohydrides [362]. They are also called *boranates* or *tetrahydroborates*. Most of these ionic compounds are solids, but one of them, aluminum boranate,  $\text{Al}(\text{BH}_4)_3$ , with covalent and hydrogen bonds, is a liquid. Metal boranates can be used as rocket propellant fuels either in solution or dispersion in liquid fuels or as solids in solid or hybrid propellants.

Ionic boron hydrides would have the advantage over covalent boron hydrides that they have lower vapor pressure or no measurable vapor pressure at all, making them safer to handle, yet they still would be useful as rocket fuels.

The direct synthesis of metal borohydrides from the elements at substantially elevated pressures and temperatures was claimed for borohydrides of Li, Na, K, Mg, and Ba. In practice only indirect methods are used for the synthesis of metal borohydrides [363]. Four different methods can be used for the preparation of metal borohydrides: **(1)** addition of diborane to metal hydrides, **(2)** reaction of diborane with metal alkyls or metal alkoxides, **(3)** reaction of metal hydrides with boron compounds, and **(4)** exchange reactions between metal borohydrides and other metals salts, mostly halides. Complex borohydrides can be used in solid propellants, in hypergolic ignition formulations, or for the production of other borohydrides and boranes.

Ionic boron hydrides are widely used as reducing agents in organic chemistry [364]. Physical properties of complex borohydrides are summarized in Tables 21 and 22.

**Table 21:** Physical properties of complex borohydrides.

| Compound              | Gross formula   | Molecular mass | Melting point, °C | Density, g/cm <sup>3</sup> | Specific heat, cal g <sup>-1</sup> °C <sup>-1</sup> | Enthalpy of formation $\Delta H_f^{298}$ , kcal/mol |
|-----------------------|-----------------|----------------|-------------------|----------------------------|-----------------------------------------------------|-----------------------------------------------------|
| Lithium borohydride   | $\text{LiBH}_4$ | 21.79          | 284 (Dec.)        | 0.66                       | 0.84                                                | -44.1                                               |
| Sodium borohydride    | $\text{NaBH}_4$ | 37.86          | Dec. >400         | 1.074                      | 0.55                                                | -43.83                                              |
| Potassium borohydride | $\text{KBH}_4$  | 53.95          | Dec. >400         | 1.175                      | —                                                   | -57.7                                               |

Data source: [365]

### 5.1.1 Lithium Borohydride

Lithium borohydride, lithium boranate, lithium tetrahydroborate, LiBH<sub>4</sub>, CAS RN [16949-15-8],  $M = 21.784$  g/mol, has a very high hydrogen content, 18.5 mass-% hydrogen. Lithium boranate is a white powder, which, in contradistinction to sodium boranate, reacts with water. At room temperature, diborane is readily absorbed into ethyllithium with the formation of various ethyldiboranes and a white solid, which is LiBH<sub>4</sub> [366]. LiBH<sub>4</sub> can be synthesized by several methods, for example, direct synthesis from elements. Other methods of preparing lithium borohydride are:

or

or

#### 5.1.1.1 Physical Properties of Lithium Borohydride

The crystal structure of LiBH<sub>4</sub> has been studied by synchrotron X-ray powder diffraction at room temperature and at 408 K [367]. At room temperature it has orthorhombic symmetry, space group *Pmna*, with unit cell parameters of  $a = 7.17858(4)$  Å,  $b = 4.43686(2)$  Å,  $c = 6.80321(4)$  Å. The tetrahedral (BH<sub>4</sub>)<sup>−</sup> anions (point symmetry *m*) are aligned along two orthogonal directions and are strongly distorted with respect to bond lengths [B—H = 1.04(2) to 1.28(1) Å] and bond angles [ $\angle$ H—B—H = 85.1(9)° and 120.1(9)°]. As the temperature is increased the structure undergoes a first-order transition and becomes hexagonal (space group *P6<sub>3</sub>mc*, with unit cell parameters of  $a = 4.27631(5)$  Å,  $c = 6.94844(8)$  Å at  $T = 408$  K). The (BH<sub>4</sub>)<sup>−</sup> tetrahedra align along *c*, become more symmetric [point symmetry *3m*, B—H = 1.27(2) and 1.29(2) Å,  $\angle$ H—B—H = 106.4(2)° and 112.4(9)°], and show displacement amplitudes that are consistent with dynamical disorder about their trigonal axis. Structurally, LiBH<sub>4</sub> has four different polymorph phases with the space groups *Pnma*, *P6<sub>3</sub>mc*, *Ama2*, and *Fm-3m*. Dynamically, the high temperature phase of LiBH<sub>4</sub> is a lithium fast-ion conductor.

The standard enthalpy of formation of lithium borohydride is −190.46 kJ/mol (−45.5 kcal/mol). Other sources gave an enthalpy of formation of −194 kJ/mol (−46.4 kcal/mol).

### 5.1.1.2 Chemical Properties of Lithium Borohydride

Lithium borohydride is hygroscopic and unstable in moist air. The reaction between lithium borohydride  $\text{LiBH}_4$  and atmospheric water vapor leads to premature material dehydrogenation and unwanted gas evolution in propellants. Lithium borohydride can be protected from the moisture by chemical vapor deposition metal coatings deposited from metal carbonyl decomposition [368].

Lithium borohydride can be dissolved in ammonia and this solution constitutes a hypergolic fuel [369, 370]. Lithium boranate forms adducts with ammonia in stoichiometric compositions, containing one or two ammonia molecules as solvates:  $\text{LiBH}_4 \cdot \text{NH}_3$  or  $\text{LiBH}_4 \cdot 2\text{NH}_3$ .

Lithium borohydride is considered as a hydrogen storage material owing to its high gravimetric hydrogen density (19.6%). Because of its hygroscopicity, lithium borohydride is a hazardous material that requires specific handling precautions. The reaction mechanism between  $\text{LiBH}_4$  and atmospheric water vapor, which leads to premature material dehydrogenation, was investigated using X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, XRD, or thermogravimetric analysis (TGA)/differential thermal analysis (DTA), were investigated and led to the formation of lithium metaborate dihydrate  $\text{LiBO}_2 \cdot 2\text{H}_2\text{O}$  as hydrolysis product [371].

Lithium borohydride  $\text{LiBH}_4$  was introduced as an energetic component in solid propellants for its high hydrogen content, perfect burning performance and high reactivity. In order to reduce the hygroscopicity and to improve the stability in air,  $\text{LiBH}_4$  was coated with wax and polyester carbonate [372, 373]. The final product was characterized by scanning electron microscopy, electron spectroscopy for chemical analysis-XPS, and Raman spectroscopy, whereas the stability in air was investigated by monitoring weight changes. The results showed that a uniform coating layer was formed on the surface of  $\text{LiBH}_4$ , and the coverage was estimated from the boron content as approximately 82%. The activity of  $\text{LiBH}_4$  as an additive to promote the thermal decomposition of 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX) and ammonium perchlorate was studied using differential scanning calorimetry (DSC), comparing the catalytic effects of pure and coated  $\text{LiBH}_4$ . This indicated that the coating did not decrease the reactivity of  $\text{LiBH}_4$ . It was suggested that surface coating with inert materials is a simple and effective method of improving the storage stability and performance of  $\text{LiBH}_4$ , while maintaining its reactivity.

### 5.1.1.3 Applications for Lithium Borohydride

Lithium borohydride would not only be a good fuel in rocket propellants, but it has also been considered as a hydrogen storage medium because it has high gravimetric hydrogen capacity [374]. In the hydrolysis of  $\text{LiBH}_4$  with the liberation of hydrogen gas, different byproducts form under different operating conditions. In the hydrogen desorption reaction of  $\text{LiBH}_4$ ,  $\text{Li}_2\text{B}_{12}\text{H}_{12}$  is a possible intermediate compound. Several methods have been proposed to improve the de-/rehydrogenation properties of  $\text{LiBH}_4$ . The first method is the “destabilization” of  $\text{LiBH}_4$ . The second method is the use of catalysts.

### 5.1.2 Sodium Borohydride

Sodium borohydride, sodium boranate, sodium tetrahydroborate,  $\text{NaBH}_4$ ,  $M = 37.833 \text{ g/mol}$ , CAS RN [16940-66-2], has a moderately high hydrogen content of 10.66 mass-% hydrogen. The hydrogen can be released by reaction with catalysts and water. Sodium borohydride is unusual because it is soluble in water without hydrolysis.

The standard enthalpy of formation of sodium borohydride is  $-191.84 \text{ kJ/mol}$  ( $-45.8 \text{ kcal/mol}$ ).

Sodium borohydride,  $\text{NaBH}_4$ , an air-stable white powder commonly referred to as sodium borohydride, is the most commercialized and readily available boron hydride material. Sodium borohydride or potassium borohydride do not react with water and are soluble in water. They are stable in aqueous solution as long as the pH does not drop into the acidic range and as long as contact with catalysts is avoided. Sodium borohydride is widely used as a reductant in organic chemistry, as a catalyst, and for bleaching high-brightness paper. Using sodium borohydride as a hydrogen storage medium for hydrogen-propelled automobiles is only economical if a simple method of converting the hydrolysis products back to sodium borohydride can be found.

Sodium borohydride can be prepared by electrolytic or hydrogen gas reduction of borax or other boron minerals. Reduction of sodium metaborate with magnesium produces sodium borohydride. Sodium borohydride, an important starting reactant in the preparation of boranes, can be prepared by the high-temperature reaction of sodium hydride with borate esters [375]. It is a very useful reducing agent for a wide range of industrial applications [376]. Various applications of sodium borohydride in the hypergolization of kerosene fuels will be discussed in a future volume on hypergolic propellants. See also [377, 378].

### 5.1.3 Magnesium Borohydride

Magnesium borohydride, magnesium bis(tetrahydroborate),  $\text{Mg}(\text{BH}_4)_2$ , is a potential rocket fuel, but very little is known about it. Metal tetrahydroborates, in general, form a large variety of structures ranging from simple ionic structures for  $\text{NaBH}_4$  to very complex structures for  $\text{Mg}(\text{BH}_4)_2$ . Despite the extensive discussion in the literature no clear explanation has been offered for this variety so far. A DFT computational analysis of the structural and electronic properties of a broad range of metal tetrahydroborates was done to study the factors that determine their structure: ionic bonding, the orientation of the  $\text{BH}_4$  groups, and the coordination number of the metal cation [379]. The charge transfer in the metal tetrahydroborates explains the structural diversity of these ionic compounds. By using the ionic radius for the  $\text{BH}_4$  group, structural predictions can be made for new and complex metal hydride compounds. The structure of magnesium borohydride is a transition between ionic and covalent borohydrides.

Magnesium borohydride has been evaluated as a hydrogen storage medium. Magnesium borohydride has the most complex crystal structures and the largest number

of phase polymorphs among other borohydrides. Some of these polymorphs possess a significant porosity, and on the other hand ultra-density with the second highest volumetric hydrogen content among all known hydrides. Additionally,  $\text{Mg}(\text{BH}_4)_2$  has the lowest theoretical stability, the lowest temperature of hydrogen release, and the mildest conditions for partial rehydrogenation among the alkali and alkaline-earth borohydrides [380].

#### 5.1.4 Other Ionic Boron Hydrides

Ionic boron hydrides would have the advantage over covalent boron hydrides that they have lower vapor pressure or no measurable vapor pressure at all, making them safer to handle and they still would be useful as rocket fuels.

In the thermolysis of tetraethylammonium tetraborohydride,  $\text{Et}_4\text{NBH}_4$ , the tetraethylammonium cation seems to survive, but the tetraborohydride anion changes to form di-tetraethylammonium decahydrodecaborate,  $(\text{Et}_4\text{N})_2\text{B}_{10}\text{H}_{10}$  [381]. Thermolysis of  $\text{Et}_4\text{NBH}_4$  can be done using triethylamine borane ( $\text{Et}_3\text{NBH}_3$ ) as a boron-based solvent or using mineral oil as a non-boron-based solvent. See also [382, 383].

A series of hypergolic metal ( $\text{Cu}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Zn}^{2+}$ ) complexes with  $\text{B}_{12}\text{H}_{12}^{2-}$  were synthesized and fully characterized [384]. These complex metal hydrides possess good physicochemical properties (decomposition temperatures: 494.9–559.4 K (221.8–286.3 °C); densities: 1.215–1.264 g/cm<sup>3</sup>). Two of these six complexes exhibited ultrashort ignition delay times (approximately 1 ms), with white fuming nitric acid (WFNA) as the oxidizer, which makes them useful for bipropellant formulations.

## 5.2 Covalent Complex Boron Hydrides

### 5.2.1 Beryllium Borohydride

Beryllium borohydride, beryllium boranate; beryllium, bis[tetrahydroborato];  $\text{Be}(\text{BH}_4)_2$ ,  $M = 38.7$  g/mol, CAS RN [30374-53-9], is a solid that readily sublimates without decomposition.

Beryllium borohydride,  $\text{Be}(\text{BH}_4)_2$ , can be prepared from dimethylberyllium and diborane [385]:

or, even better, from beryllium chloride and lithium borohydride or from beryllium chloride and sodium borohydride in a dry melt reaction at 323–423 K (50–150 °C) under nitrogen and at low pressure [386].

The vapors were collected in a cold trap, yielding 89% of theoretical of beryllium borohydride of high purity. Beryllium borohydride is a white solid that sublimates at room temperature, ignites instantly in air and reacts vigorously with water.

Beryllium borohydride forms 1:1 adducts with diethyl ether or trimethylamine. The ether adduct  $\text{Be}(\text{BH}_4)_2 \cdot \text{O}(\text{C}_2\text{H}_5)_2$ , is a clear liquid that distills at 323 K at 0.13 Pa (50 °C at 0.001 mm Hg). The amine adduct,  $\text{Be}(\text{BH}_4)_2 \cdot \text{N}(\text{CH}_3)_3$ , is a low melting solid that melts at ~308 K (~35 °C). The amine adduct reacts further with additional  $\text{Me}_3\text{N}$ :

Under intense heat, the adducts decompose to hydrogen, diborane, and beryllium-bearing solids.

Studies of the  $\text{Be}(\text{BH}_4)_2/\text{AlR}_3$  reaction system led to the discovery of new forms of beryllium hydride, the borane-terminated beryllium hydrides,  $\text{H}_3\text{B}(\text{BeH}_2)_x\text{BH}_3$  [387]. These compounds have good physical and chemical stability and are essentially equivalent to pure  $\text{BeH}_2$  in theoretical propellant performance. They are, like  $\text{BeH}_2$ , amorphous and of low density, and studies aimed at inducing  $\text{H}_3\text{B}(\text{BeH}_2)_x\text{BH}_3$  crystallization met with very limited success.

### 5.2.1.1 Properties of Beryllium Borohydride

The vapor pressure of beryllium borohydride can be calculated from:

$$\log_{10} p = 11.772 - \frac{3240}{T}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The normal sublimation temperature at sea level pressure is 364.4 K (91.3 °C) and the heat of vaporization is 62.0 kJ/mol (14.81 kcal/mol) [385]. The vapor pressure of the trimethylamine adduct with beryllium borohydride can be calculated from:

$$\log_{10} p = 8.353 - \frac{2909}{T}$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin and which gives an extrapolated b. p. of 533 K (260 °C).

The crystal structure of  $\text{Be}(\text{BH}_4)_2$  consists of a helical polymer of  $\text{BH}_4\text{Be}$  and  $\text{BH}_4$  units [388]. Within the  $\text{BH}_4\text{Be}$  unit the  $\text{Be} \cdots \text{B}$  distance is  $1.918 \pm 0.004 \text{ \AA}$ , whereas each Be is linked to two remaining  $\text{BH}_4$  units (and each  $\text{BH}_4$  to two Be) at a  $\text{Be} \cdots \text{B}$  distance of  $2.001 \pm 0.004 \text{ \AA}$ . Within the  $\text{BH}_4\text{Be}$  units there are two hydrogen bridges between B and Be, and in the helical polymer each  $\text{B} \cdots \text{Be}$  contact has two hydrogen bridges. The crystal structure is tetragonal, and the space group is  $I41cd$ , with  $a = 13.62 \pm 0.01 \text{ \AA}$  and  $b = 9.10 \pm 0.01 \text{ \AA}$ . Bonding from Be to  $\text{BH}_4$  occurs about equally directly from Be to B compared with bonding through bridge hydrogen atoms.

A first-principles study of the electronic structure and the energetics of beryllium boranate  $\text{Be}(\text{BH}_4)_2$  showed that (in contrast to the other boranates and alanates) hydrogen desorption directly to the elements is likely and is at least competitive with desorption to the elemental hydride ( $\text{BeH}_2$ ) [389]. The low formation enthalpy of  $\text{Be}(\text{BH}_4)_2$  indicated participation of all atoms in the covalent bonding, which is in contrast to the ionic bonding observed in other boranates.  $\text{Be}(\text{BH}_4)_2$  differs from other boranates and alanates in that its dehydrogenation to the elements is thermodynamically slightly more favorable than dehydrogenation via the simple hydride  $\text{BeH}_2$ . In alkali or alkaline earth boranates and alanates, dehydrogenations always occur via the alkali or alkaline earth simple hydride. Boranates are more stable than the corresponding alanates, lighter cations give compounds that are more unstable, and alkaline earth compounds are more unstable than alkali compounds.

### 5.2.1.2 Properties of Hybaline B3

Physical properties of the liquid adduct of methylamine and beryllium borohydride, which has been developed and tested under the code-name Hybaline B3, are summarized in Table 23.

**Table 23:** Physical properties of Hybaline B3.

| Property                 | SI units                                 | Other units                                 |
|--------------------------|------------------------------------------|---------------------------------------------|
| Freezing point           | 261.6 K                                  | −11.5 °C                                    |

Data source: [390]

There is contradicting information about the pyrophoricity of Hybaline B3. Although one source states that it oxidizes slowly in dry air without ignition, other sources describe it as instantly pyrophoric in air.

The liquid adduct of methylamine and beryllium borohydride under the code-name Hybaline B3 has been the fuel for 87 test firings in a nominal 440-N (100 lb<sub>f</sub>) thrust uncooled rocket engine at a chamber pressure of 2.07 MPa (300 psia) [390, 391]. Thirty-seven tests were carried out with  $\text{N}_2\text{O}_4$ , 43 with 90%  $\text{H}_2\text{O}_2$ , and 7 with 98%  $\text{H}_2\text{O}_2$  as the oxidizer. An additional 25 tests were conducted with  $\text{N}_2\text{O}_4$  at a thrust level of 2.2 kN (500 lb<sub>f</sub>) and a chamber pressure of 6.89 MPa (1000 psia). Delivered performance with both oxidizers was low compared with theoretical impulse. Performance

efficiencies significantly increased at weight oxidizer/fuel ratios where the combustion temperature was near or above the melting point of beryllium oxide. Hybaline B3 was compatible with standard materials of construction, and although it is pyrophoric, the fuel presented few handling problems other than toxicity.

### 5.2.2 Aluminum Borohydride

Aluminum borohydride, also known as aluminum boranate, aluminum tetrahydroborate, aluminum tris(tetrahydroborate),  $\text{Al}(\text{BH}_4)_3$ ,  $\text{AlB}_3\text{H}_{12}$ ,  $M = 71.510 \text{ g/mol}$ , CAS RN [16962-07-5], is a liquid instead of a solid and reacts vigorously with air, oxygen, or water. Aluminum borohydride can be used as an ignition fluid for large rocket engines with LOX as the oxidizer.

#### 5.2.2.1 Preparation of Aluminum Borohydride

Aluminum borohydride was first prepared from trimethylaluminum and excess diborane [392]:

Aluminum boranate and other borohydrides can be prepared by metathetical reactions from metal halogenides utilizing the alkali metal borohydrides [393, 394]:

where X is a halogen (Cl, Br) and M is an alkali metal (Li, Na, K). The THF adduct of aluminum boranate is not pyrophoric.

#### 5.2.2.2 Physical Properties of Aluminum Boranate

The molecular mass of aluminum boranate is  $71.510 \text{ g/mol} = 13.9841 \text{ mol/kg}$ .

#### Melting Point and Boiling Point of Aluminum Boranate

Aluminum boranate freezes at  $208.6 \text{ K} = -64.5^\circ\text{C}$  and boils at  $317.6 \text{ K} = 44.5^\circ\text{C}$ . The solid  $\text{Al}(\text{BH}_4)_3$  exists in two modifications with a phase transition temperature between 180 and 195 K ( $-93$  and  $-78^\circ\text{C}$ ). Weak interactions between aluminum borohydride molecules in the solid state explain the low melting point of the material.

#### Density of Aluminum Boranate

The density of aluminum boranate is less than that of water ( $\rho = 0.544 \text{ g/cm}^3$  at  $293 \text{ K} = 20^\circ\text{C}$ ). The density data for aluminum boranate are listed in Table 24.

**Table 24:** Density of aluminum boranate.

| Temperature |       | Density           |
|-------------|-------|-------------------|
| K           | °C    | g/cm <sup>3</sup> |
| 209.2       | −63.9 | 0.622             |
| 209.7       | −63.4 | 0.622             |
| 223.0       | −50.1 | 0.611             |
| 235.9       | −37.2 | 0.600             |
| 241.5       | −31.6 | 0.595             |
| 245.6       | −27.5 | 0.592             |
| 259.7       | −13.4 | 0.581             |
| 259.9       | −13.2 | 0.581             |
| 266.3       | −6.8  | 0.576             |
| 266.5       | −6.6  | 0.576             |
| 274.1       | +1.0  | 0.569             |
| 274.5       | +1.4  | 0.569             |

Data source: [52]

The data in Table 24 can be represented by the equation:

$$\rho = 0.7866 - 0.000793T$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin.

### Vapor Pressure of Aluminum Boranate

Vapor pressure data for aluminum boranate are listed in Table 25.

**Table 25:** Vapor pressure of aluminum boranate.

| Temperature |       |       | Vapor pressure |       |       |
|-------------|-------|-------|----------------|-------|-------|
| K           | °C    | °F    | kPa            | mm Hg | psia  |
| 231.2       | −41.9 | −43.4 | 1.5            | 11.0  | 0.213 |

Data source: [310]

### Viscosity of Aluminum Boranate

The viscosity of aluminum borohydride was determined experimentally from 209.2 to 305.6 K (−63.9 to 32.5 °C) with an accuracy of  $\pm 2.5\%$ . The data are given in Table 26 and were plotted in Figure 4 (located above in the diborane section).

**Table 26:** Viscosity of liquid aluminum borohydride.

| Temperature |       | Density           | Viscosity  |
|-------------|-------|-------------------|------------|
| K           | °C    | g/cm <sup>3</sup> | millipoise |
| 209.3       | −63.8 | 0.620             | 9.28       |
| 217.3       | −55.8 | 0.614             | 7.58       |
| 228.9       | −44.2 | 0.605             | 5.91       |
| 239.6       | −33.5 | 0.597             | 4.69       |
| 250.3       | −22.8 | 0.588             | 3.93       |
| 261.7       | −11.4 | 0.581             | 3.39       |
| 265.0       | −8.1  | 0.577             | 3.12       |
| 280.5       | 7.4   | 0.564             | 2.58       |
| 287.4       | 14.3  | 0.559             | 2.34       |
| 305.6       | 32.5  | 0.545             | 1.93       |

Data source: [52]

The viscosity of liquid aluminum borohydride, the same data as shown in Table 26 and in Figure 4 (located in the diborane section), as a function of temperature can be expressed by the equation [52]:

$$\eta = 23 \times 10^{-5} \rho^{\frac{1}{3}} e^{\left(\frac{1291}{\rho T}\right)}$$

where  $\eta$  is the viscosity in Poise,  $\rho$  is the density in g/cm<sup>3</sup>, and  $T$  is the temperature in kelvin.

### Surface Tension of Aluminum Boranate

The surface tension of aluminum boranate was measured within the range 209 to 305 K (−63 to +32 °C). The surface tension data were already shown in Figure 6 (in the diborane section). The numeric surface tension data are listed in Table 27.

The data in Table 27 can be fitted to a linear equation:

$$\sigma = (61.0 - 0.130T)\rho^{\frac{2}{3}}$$

where  $\sigma$  is the surface tension in dyn/cm,  $\rho$  is the density in g/cm<sup>3</sup>, and  $T$  is the temperature in kelvin.

**Table 27:** Surface tension of aluminum boranate.

| Temperature |       | Surface tension     |
|-------------|-------|---------------------|
| K           | °C    | dyn/cm <sup>a</sup> |
| 209.6       | −63.5 | 24.6                |
| 216.2       | −56.9 | 23.8                |
| 227.4       | −45.7 | 22.6                |
| 238.3       | −34.8 | 21.3                |
| 248.9       | −24.2 | 20.0                |
| 258.7       | −14.4 | 19.0                |
| 260.3       | −12.8 | 18.8                |
| 263.7       | −9.4  | 18.6                |
| 286.8       | +13.7 | 16.0                |
| 305.1       | +32.0 | 14.3                |

### IR Spectra of Aluminum Boranate

High-resolution ( $0.01\text{ cm}^{-1}$ ) Fourier transform infrared (FTIR) spectra of  $\text{Al}(\text{BH}_4)_3$  and  $\text{Al}(\text{BD}_4)_3$  recorded from low-pressure samples at room temperature showed only broad vibrational bands, with no trace of resolved rotational structure [395]. The BH bridge stretching and the  $\text{BH}_2$  deformation regions were examined at  $0.001\text{ cm}^{-1}$  resolution by tunable infrared diode laser spectroscopy for samples cooled to  $\sim 10\text{ K}$ . These too showed only near continua, with much more congestion than predicted by non-rigid rotor simulations based on boron isotopic shifts from *ab initio* calculations.

The normal mode frequencies and corresponding vibrational assignments of aluminum tetrahydroborate in  $D_3$  symmetry were examined theoretically [396]. All normal modes were successfully assigned to one of seven types of motion (B—H stretch, Al—B stretch, B—Al—B bend, H—B—H bend,  $\text{BH}_4$  wag,  $\text{BH}_4$  rock and  $\text{BH}_4$  twist) predicted by a group theoretical analysis. By comparing the vibrational frequencies with IR and Raman spectra available in the literature, a set of scaling factors was derived.

### Raman Spectra of Aluminum Boranate

Raman spectra of  $\text{Al}(\text{BH}_4)_3$  and  $^{11}\text{B}$  and  $^2\text{H}$  isotope-labeled isomers appeared to confirm a prismatic bridge structure  $D_{3h}$  [397]. There was no evidence for any significant structural change in the different phases when comparing IR spectra of gaseous, solid, and matrix-isolated IR spectra of  $\text{Al}(\text{BH}_4)_3$  and  $\text{Al}(\text{BD}_4)_3$  [398]. The data were consistent with a  $D_{3h}$  prismatic structure and all 23 of the optically allowed fundamental transitions were assigned for each molecular isotope. Some correlated NMR-Raman spectra were obtained over the temperature range 213 to 353 K ( $-60$  to  $+80\text{ }^\circ\text{C}$ ) and the results suggested that traces of decomposition products may act in a catalytic manner to profoundly change the NMR spectra of  $\text{Al}(\text{BH}_4)_3$ .

### Molecular Structure of Aluminum Boranate

The structures of several modifications of solid aluminum tetrahydroborates have been investigated, primarily by XRD of single crystals at low temperatures [399]. Solid aluminum tris(tetrahydroborate) exists in two phases with a transition temperature within the range 180–195 K. Each phase is made up of discrete  $\text{Al}(\text{BH}_4)_3$  units in which the angle between  $\text{AlB}_2$  and  $\text{Al}(\mu\text{-H})_2\text{B}$  planes is close to  $90^\circ$  and which conform within the limits of experimental error to  $D_{3h}$  symmetry; in the  $\alpha$  phase these molecular units are disposed around a  $2_1$  crystallographic screw axis.

### Thermodynamic Properties of Aluminum Boranate

The heat of formation of aluminum boranate was determined by calorimetry [400]. The enthalpy of formation of liquid aluminum boranate is  $-312.5 \text{ kJ/mol} = -74.7 \text{ kcal/mol}$  [52].

#### 5.2.2.3 Chemical Properties of Aluminum Boranate

##### Autoignition of Aluminum Boranate

There are numerous proposals for using aluminum boranate as the hypergolic ignition source for LOX-based rocket propellant applications and as a fuel in air-breathing hypersonic ramjets. The autoignition of aluminum boranate was therefore examined under a variety of conditions at different pressures and temperatures.

Additional experiments with aluminum boranate ignition and combustion will be described in a future volume on hypergolic bipropellant combinations. See also Fletcher et al. [401–404].

Here is one of the most unusual applications of a pyrophoric fluid: one can see why someone would want to select aluminum boranate for ignition of a rocket engine, but patenting aluminum boranate for use in a cigarette lighter appears to be extremely risky, a sure method of eradicating smokers by triggering accidental explosions of their lighters [405].

##### Reactions of Aluminum Boranate with Lewis Bases

Aluminum boranate forms adducts with amines and ethers. The adduct of aluminum boranate with dimethylamine is a liquid and has been tested as a rocket propellant under the code name Hybaline A4. Hybaline A4 is the reaction product of aluminum boranate and dimethylamine and was developed by Union Carbide [406]. The reaction was carried out in an inert solvent such as n-hexane or benzene. Hybaline A4 oxidizes slowly in dry air, but inflames in moist air or in contact with water. It has a very low vapor pressure, 267 Pa at 298 K = 2 mm Hg at  $25^\circ\text{C}$ , which makes it safer to handle than pentaborane. The boiling point was estimated at  $>493 \text{ K}$  ( $>220^\circ\text{C}$ ), but starts to decompose at that temperature. The freezing point is 265.6 K ( $-7.5^\circ\text{C}$ ) with supercooling. Once solidified, it melts at 277.6 K ( $+4.5^\circ\text{C}$ ). The density of Hybaline A4 is  $0.759 \text{ g/cm}^3$ . The viscosity of Hybaline A4 at 293 K is 9.2 cPs. The enthalpy of formation is  $-69 \text{ kJ/mol}$  ( $-16.5 \text{ kcal/mol}$ ).

A similar adduct can be formed between aluminum boranate and a 1:1 mol ratio mixture of dimethylamine and methylamine. This adduct has been evaluated as a rocket propellant under the code name Hybaline A5. Most of its properties are similar to those of Hybaline A4, but it has a lower freezing point than Hybaline A4. As a matter of fact, it has no sharp freezing point, but solidifies to a glassy sticky mess below 233 K ( $-40^{\circ}\text{C}$ ). The heat of formation of liquid Hybaline A4 was determined by oxygen bomb calorimetry [400].

Although this fuel has never found widespread application, substantial effort has been devoted to developing materials of construction that are compatible with Hybaline A. O-ring seals of selected elastomeric and compliant materials were evaluated for resistance to Hybaline A5 and pentaborane in a simulated end-use test at 296 K ( $73^{\circ}\text{F}$ ) [407]. The candidate elastomers were placed under compression in closed cells and exposed to the liquid and vapor of liquid rocket fuels and oxidizers for extended periods of time. Rate of fuel loss through the seal, and the change in physical properties of the seal materials were determined.

Compatibility and corrosion rates of 15 structural metals and three fluorinated plastics in Hybaline A5 liquid and vapor at 323 K ( $50^{\circ}\text{C}$ ) were investigated [408]. Corrosion rates of all metals were low ( $2.5\text{ }\mu\text{m}/\text{year} = 0.1\text{ mil}/\text{year}$  average). None of the metals actively catalyzed the decomposition of Hybaline A5. The plastics showed weight gains of 0.02 to 0.04% in 21-day exposures, and insignificant changes in appearance. No significant change in mechanical properties on 20-cm (8-in.) tensile specimens and no stress corrosion cracking on U-bend stressed specimens occurred.

Extensive materials compatibility testing was done on newly developed materials and other, well established materials that had already shown good compatibility with other rocket propellants. Several polymers were examined for resistance to Hybaline A5 and gelled aluminum/hydrazine [409, 410].

Hybaline  $\text{A}_{14}$  is similar to Hybaline A5 except that the amine ligand is different to assure better compatibility with RP-1. The amine ligand is 2-ethylhexylamine. It freezes below 195 K ( $-78^{\circ}\text{C}$ ) and has a density of  $0.78\text{ g}/\text{cm}^3$  at 293 K. It autoignites in air only above 373 K ( $100^{\circ}\text{C}$ ) and is best stored under nitrogen. Hybaline  $\text{A}_{14}$  is hypergolic with most oxidizers. It is more viscous than Hybaline A5 with a viscosity of 30 cPs at 293 K. Hybaline  $\text{A}_{14}$  has been tested as a combustion instability suppressant in a LOX/RP-1 rocket combustion chamber [411]. Hybaline A3 was a mixture of methylamine with aluminum boranate.

Propellant combinations of Hybaline A5 with six different oxidizers ( $\text{N}_2\text{O}_4$ ,  $\text{N}_2\text{O}_4 + \text{NO}$ , inhibited red fuming nitric acid (IRFNA),  $\text{H}_2\text{O}_2$ ,  $\text{ClF}_5$ , and  $\text{F}_2$ ) were evaluated in terms of the effects of engine design parameters on their ignition characteristics at reduced ambient pressures. Additional applications of Hybalines as fuels in hypergolic rocket propellant combinations will be discussed in a future volume on hypergolic bipropellant combinations.

Aluminum borohydride forms adducts with 1–4 mol ethylenediamine that have been evaluated as hydrogen storage media [412].

### Reactions of Aluminum Boranate with Other Hydrides

Aluminum boranate reacts with a wide range of metal borohydrides, forming solid complex hydrides. The adduct of aluminum boranate with ammonia borane has been well characterized and evaluated as a hydrogen storage medium, but it decomposed to a viscous mass within 2 weeks of storage at room temperature. The advantage of this adduct as a hydrogen storage medium would be that it releases two moles of dihydrogen at moderate temperatures, although only stepwise, and its decomposition leading to release of dihydrogen is endothermic instead of exothermic, such as that of ammonia borane [413].

### Thermal Stability of Aluminum Boranate

In aluminum borohydride, the decomposition and the release of hydrogen start at around 313 K (40 °C). The material has not been investigated in detail for hydrogen storage by reversible reactions because of its extreme sensitivity to water and air.

The thermodynamical stability of  $\text{Al}(\text{BH}_4)_3$  has been investigated using first-principles calculations based on DFT and the heat of formation was predicted to be  $-132 \text{ kJ/mol}$  [414].

### Handling of Metal Borohydrides

When handling solid metal borohydrides (and other metal hydrides) in the laboratory, one should protect oneself from the dust by wearing dust masks and goggles because the finely ground dust particles are very fluffy and easily become airborne, irritating the mucous membranes.

In the case of metal borohydride fires, the fires may not be extinguished with water because hydrogen evolution would cause the situation to become even more dangerous. Even carbon dioxide fire extinguishers are useless against metal hydride or metal borohydride fires. To fight metal borohydride fires, it would be best to cover the burning material with sand, which would starve the burning material of oxygen.

### Toxicity of Aluminum Boranate

Aluminum boranate would inflame instantly in air or hydrolyze with moisture before it can be absorbed into living things. Aluminum boranate adducts with alkylamines, known under the code name Hybaline, are more stable and can potentially accidentally find their way into propellant handling personnel. Hybaline A, an adduct of aluminum boranate with alkylamines, has been administered to rats, rabbits, cats, and dogs via intragastric, *i.p.*, *i.v.*, cutaneous, subcutaneous, and inhalation routes [415]. All data indicated that effects of Hybaline A on mammals can be attributed to physiochemical changes caused by energy production during hydrolysis or thermal decomposition of Hybaline A. Those animals that survived the initial exposure showed no changes in any system that could be attributed to Hybaline A.

## 6 Borazines, Borazanes, and Boroxines

In addition to boron organic compounds containing only boron, carbon, and hydrogen, there are other compounds to be investigated as candidate rocket fuels that contain nitrogen as well.

### 6.1 Borazines (Borazoles)

A ring structure formed of alternating boron and nitrogen atoms is isoelectronically similar to cyclohexane and benzene. These rings are called borazines, sometimes also called borazoles, although the name borazine is the more widely accepted nomenclature [416]. The name **borazole** hints at its structural similarity with benzene (*Benzol* in German).

Borazine is easier to handle than pentaborane, but its heat of combustion and performance as a rocket fuel is lower than that of pentaborane.

Borazine, also known as borazole,  $B_3N_3H_6$ , 1,3,5-triaza-2,4,6-triborinane, CAS RN [6569-51-3], with a molecular mass of 80.5 g/mol, contains 52.2 mass-% nitrogen and 40.2 mass-% boron. It freezes at 220 K ( $-58^\circ\text{C}$ ) and boils at 326 K ( $53^\circ\text{C}$ ). The density at 273 K ( $0^\circ\text{C}$ ) is  $0.824\text{ g/cm}^3$ . The vapor pressure of borazine in the range 223–325 K can be calculated from:

$$\log p_v = 6.5022 - \frac{960.099}{(T - 63.32)}$$

where  $p_v$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The six B–N bonds have lengths of  $1.436\text{ \AA}$ . For comparison, the carbon-carbon bonds in benzene are shorter at  $1.397\text{ \AA}$ .

Borazine was initially prepared by thermolysis of the DADB, which was obtained from diborane and ammonia [417]:

Borazine can be prepared by interaction of  $LiBH_4$  and  $NH_4Cl$  in the absence of solvents at moderately high temperatures [418].

This method is preferred as it does not use high pressure. A similar method used the cheaper sodium borohydride and ammonium sulfate in diglyme as a solvent [419].

A four-step procedure involving the reaction of  $B_2H_6$  with liquid  $NH_3$  to give borazine is described in [420].

In a two-step process to borazine, boron trichloride is first converted to trichloroborazine [421]:

The B—Cl bonds are subsequently converted to B—H bonds:

The following density, viscosity, and surface tension data of borazine were taken from Eddy et al. [422]. The density of borazine as a function of temperature can be expressed by:

$$\rho = 1.1551 - 0.001074T$$

where  $\rho$  is the density in  $g/cm^3$  and  $T$  is the temperature in kelvin. Data for the viscosity of borazine were curve-fitted to the equation:

$$\eta = 47.3(10^{-5})\rho^{\frac{1}{3}}e^{665.5\frac{\rho}{T}}$$

where  $\eta$  is the viscosity in Poise,  $\rho$  is the density in  $g/cm^3$  and  $T$  is the temperature in kelvin. Just as check points for the equation above, here are three raw data points for three temperatures: 230 K: 6.39 mPs; 273 K: 3.65 mPs; and 300 K: 2.85 mPs. Data for the surface tension of borazine were curve-fitted to the equation:

$$\sigma = (58.3 - 0.120T)\rho^{\frac{2}{3}}$$

where  $\sigma$  is the surface tension in dyn/cm,  $\rho$  is the density in  $g/cm^3$ , and  $T$  is the temperature in kelvin. The refractive index  $n_D^{20}$  of borazine is 1.3821. The freezing point of borazine is 216.9 K (with supercooling). Methods for the synthesis of borazine and its derivatives, synthetic methods based on reactions of functional derivatives of borazine, and properties of borazine and its derivatives are summarized in [423]. The heat of combustion of liquid borazine is  $2313.3 \pm 12.6$  kJ/mol ( $552.90 \pm 3.0$  kcal/mol), which translates into a heat of formation of  $-548.5 \pm 13.4$  kJ/mol ( $-131.1 \pm 3.2$  kcal/mol) [424].

Borazine does not react with diborane or lithium boranate, but ammonium chloride or hydrogen chloride will decompose it. Heating borazine at 343 K (70 °C) expels hydrogen with formation of a borazinyl polymer or polyborazylene, in which the monomer units are coupled in *para* position by new boron-nitrogen bonds. Boron nitride can be prepared by further heating of polyborazylene to 1273 K (1000 °C).

### 6.1.1 Substituted Borazines

In alkylborazines, the alkyl groups can be attached to either a boron atom or a nitrogen atom that is part of the ring structure:

Alkylborazines, for instance  $B,B',B''$ -triethylborazine, react hypergolically with fuming nitric acid [425]. In a ring of heterocyclic compounds, counting to indicate the location of substituents usually starts at the heteroatom. If the entire ring consists of heteroatoms, counting starts at the nitrogen (one of the nitrogen) atom(s).  $B,B',B''$ -triethylborazine could be called 2,4,6-triethylborazine.

The borazine ring undergoes some substitution reactions. However, unlike benzene, borazine and certain of its derivatives undergo addition reactions readily to give products such as  $B_3H_6N_3 \cdot 3HX$ , where  $X = Cl, Br, \text{ or } OH$  [426]. Borazine undergoes extensive decomposition in the liquid phase, even at room temperature.

$B,B',B''$ -triethylborazine decomposed below 373 K (100 °C), whereas  $B$ -trimethylborazine was reported to be stable at that temperature for extended periods.  $N$ -trimethylborazine (1,3,5-trimethylborazine) freezes at 265.6 K (−7.5 °C) and boils at 406 K (133 °C), whereas its  $B$ -substituted isomer ( $B$ -trimethylborazine, 2,4,6-trimethylborazine) melts at 304.9 K (31.8 °C) and sublimates at 393 K (120 °C). Hexamethylborazine was reported to survive treatment at 753 K (480 °C). Hexamethylborazine was more stable than phenyl or phenyl-methyl-borazoles [427]. Hexamethylborazine melts at 370 K (97 °C) and boils at 494 K (221 °C).

Attaching nitro groups to borazine would result in energetic explosives comparable with TNT [428, 429]. Similar energetic compounds are obtained by substituting three of the hydrogens in borazine with azido groups, such as in  $H_3B_3N_3(N_3)_3$  [430].

### 6.1.2 Borazanes

The nomenclature of adducts between boranes and amines is not always totally consistent. Some authors call them aminoborines in analogy to borine, others call them borazanes in analogy to alkanes.

## 6.2 Diammonia Diborane

Reaction of diborane with ammonia at low temperatures forms a non-volatile compound, stable at 353 K (80 °C), which had the composition  $B_2H_6 \cdot 2NH_3$ , also called diborane diammine or diammonia diborane. It took a while until the structure could be identified as a tetrahydroborate (borohydride) anion and a diaminoboronium cation:

## 6.3 Aminodiborane

Aminodiborane is a byproduct in the preparation of borazole from diborane and ammonia. It can be made by passing a current of “diborane diammine” at 361 K (88 °C) and atmospheric pressure through a heated tube. It can be stored at room temperature for several days without appreciable decomposition. It melts at 206.6 K (−66.5 °C) and boils at 348.3 K (75.2 °C). The structure of aminodiborane has been established by electron diffraction and turned out to be similar to that of diborane, with one bridge hydrogen replaced by an amino group:

Cyclic aminodiborane,  $NH_2B_2H_5$ , ADB, can be made from ammonia borane ( $NH_3BH_3$ , AB) and THF  $\cdot BH_3$  [431]. Ammonia diborane ( $NH_3BH_2(\mu-H)BH_3$ ) and aminoborane ( $NH_2BH_2$ ) were identified as key intermediates in the formation of aminodiborane. Elimination of molecular hydrogen occurred from an ion pair,  $[H_2B(NH_3)(THF)]^+ [BH_4]^-$ . The structure of the aminodiborane  $\cdot$  THF complex was found from X-ray single crystal analysis to be a three-dimensional array of zigzag chains of aminodiborane and THF, maintained by hydrogen and dihydrogen bonding. The  $B \cdots H \cdots B$  bridge is opened when aminodiborane and NaH react to form sodium aminodiboronate,  $Na[NH_2(BH_3)_2]$ .

The DADB,  $[H_2B(NH_3)_2][BH_4]$ , is an ionic dimer of ammonia borane. It has received much less attention in the past few decades than ammonia borane, although it has the same high hydrogen content (19.6%) [432].

## 6.4 Alkylborazanes

*N*-alkylborazanes may be called dialkylamino-borines. Others just call them by the borane and the amine from which they were formed. In either case it is important to specify if the alkyl groups are attached to the boron atom or the nitrogen atom or both. The structure of *N*-dimethylaminodiborane has been established by electron diffraction and by nuclear magnetic resonance [433]. It is equivalent to diborane in which one bridge hydrogen has been replaced by a dimethylamino group

*N*-trialkylborazanes can be obtained by reaction of trialkylboron compounds in the presence of tertiary amines [45]. Borazanes such as  $\text{RBH}_2 \cdot \text{NR}_3$  that were formed from dialkyldiboranes and tertiary amines can be used as rocket fuels [434]. *N*-triethylborazane has been patented as a rocket fuel [435].

The ignition delay and the freezing point of *N*-triethylborazane can be lowered by the addition of 2 to 25% triethylborane, tetraethyldiborane, or triethylaluminum [436]. Triethylborazane has a density of  $0.791 \text{ g/cm}^3$ , a melting point of  $269 \text{ K}$  ( $-4^\circ\text{C}$ ), and a boiling point of  $373 \text{ K}$  at  $1.6 \text{ kPa}$  ( $100^\circ\text{C}$  at  $12 \text{ mm Hg}$ ). The heat of combustion is  $47642 \text{ kJ/kg}$  ( $20500 \text{ BTU/lb}$ ). The properties of numerous adducts between alkylboranes and alkyl amines are summarized in [98].

Boric acid triamides, tris(dialkylamino)boranes, of the  $\text{B}(\text{NR}_2)_3$  type where  $\text{R}=\text{C}_1-\text{C}_4$  alkyl or  $\text{C}_3-\text{C}_4$  cycloalkyl can ignite hypergolically with fuming nitric acid and have been patented as rocket propellants [437]. *N,N*-Dimethylaminodiborane  $[(\text{CH}_3)_2\text{N}]\text{HBH}_2\text{BH}_2$  is a potential liquid rocket or ramjet fuel. For this reason this compound has been investigated in more detail than some of the other borazanes.

*N,N*-Dimethylaminodiborane can be prepared by treatment of  $\text{K}(\text{H}_3\text{C})_2\text{NBH}_3$  in diglyme with a threefold excess of  $\text{NaBH}_4$  and one half mole of iodine, which produces a solution of  $\text{Na}(\text{H}_3\text{C})_2\text{N}(\text{BH}_3)_2$  that can later be converted to  $\mu\text{-(H}_3\text{C)}_2\text{NBH}_2\text{BH}_2$  by the addition of another half mole of iodine [438].

The maximum fundamental flame velocity in air for O: B = 0.8 at  $308 \text{ K} = 35^\circ\text{C}$  is  $115 \pm 5 \text{ cm/s}$ . Its lower heat of combustion of liquid fuel to gaseous nitrogen, carbon dioxide, steam, and solid boric oxide is  $44769 \text{ kJ/kg}$  ( $10700 \text{ kcal/kg} = 19.225 \pm 100 \text{ BTU/lb}$ ) [439]. It is a liquid and its spontaneous ignition temperature in air is  $383 \text{ K}$  ( $110^\circ\text{C} = 240^\circ\text{F}$ ).

The triple point temperature of *N,N*-dimethylaminodiborane is at  $218.4 \pm 0.2 \text{ K}$ , and the heat of fusion is  $1408 \pm 30 \text{ J/mol}$  [440]. The heat capacity of liquid

*N*-dimethylaminodiborane at 277.8 K is  $158.2 \text{ J mol}^{-1} \text{ K}^{-1}$ . The heat of vaporization of *N*-dimethylaminodiborane at 271.6 K (12.6 kPa = 94.3 mm Hg) is  $30119 \pm 30 \text{ J/mol}$ . The vapor pressure in the range from 220 to 290 K can be calculated from the equation:

$$\log p = 406.5734/T + 5.2095614 \times 10^{-2}T + 1.01048 \times 10^{-5}T^2 \\ - 1.390588 \times 10^{-7}T^3 - 11.63086$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. Based on the heat of reaction of its hydrolysis, the standard enthalpy of formation of *N*-dimethylaminodiborane is  $-151.5 \pm 3.1 \text{ kJ/mol}$  ( $-36.22 \pm 0.75 \text{ kcal/mol}$ ) [441].

The far IR spectrum of *N,N*-dimethylaminodiborane showed a strong absorption band at  $420 \text{ cm}^{-1}$  and a weaker band at  $600 \text{ cm}^{-1}$  [442, 443]. A band at  $379 \text{ cm}^{-1}$  was assigned to the  $\mu\text{-H}_2$  bridge bending mode.

In trying to explain the molecular structure, a multiple origin method was used for the selection of atomic coordinates for the description of the normal vibrations of the *N*-dimethylaminodiborane molecule [444]. Symmetry considerations were used in order to obtain symmetry coordinates from these multiple origin method coordinates, and, under the assumption of a diagonal potential function, these coordinates were assigned to vibrational frequencies, which had been reported by Mann [442]. The valence force constants for the methyl-*N*-methyl framework vibrations were then calculated and the results compared with similar constants obtained from the dimethylamine molecule.

The molecular structure of *N,N*-dimethylaminodiborane has been determined from microwave spectra, including the boron-bonded hydrogen coordinates [445]. Structural parameters other than those of the hydrogens were in close agreement with earlier electron diffraction results. No internal rotation splittings were detected. The dipole moment was measured to be  $2.77 \pm 0.02 \text{ D}$ . The flame emission spectra of rocket engine plumes from engines operating on fluorine or oxygen as the oxidizer and dimethylaminodiborane as the fuel were measured in the visible and UV regions [446].

## 6.5 Boroxines

Boroxine ( $\text{B}_3\text{H}_3\text{O}_3$ ) CAS RN [289-56-5] is a six-membered, heterocyclic compound composed of alternating oxygen and boron atoms.

Boroxine derivatives (boronic anhydrides) such as trimethylboroxine make up a broader class of compounds called boroxines. These compounds are solids that are usually in equilibrium with their respective boronic acids at room temperature. Boroxine compounds are isoelectronic with benzene and, with the vacant *p*-orbital on the boron atoms, have partially aromatic character with a  $\pi$ -ring system. Boron single-bonds on boroxine compounds are mostly *s*-character. Ethyl-substituted boroxine has B—O bond lengths of 1.384 Å and B—C bond lengths of 1.565 Å. One of the most utilized boroxines is trimethylboroxine. It can be used for the synthesis of other alkylboron compounds, but has very little fuel value.

## 6.6 Ammonia Borane

Ammonia borane, borazane, also known as ammoniotrihydroborate, borane monoammoniate, ammonia borine, borine ammoniate,  $\text{H}_3\text{N}\cdot\text{BH}_3$ , CAS RN [13774-81-7], used to be a laboratory curiosity until its ability to reversibly store and release dihydrogen gas was discovered a few years ago and all of a sudden the number of publications dealing with this chemical has skyrocketed. The number of publications on ammonia borane, borohydrides, and similar boranes may soon exceed the number of publications on alkylboranes in the heyday of the Valkyrie ZIP HiCal fuels program. Dihydrogen as an energy carrier (it has been falsely called an energy source) has promises of a clean hydrogen energy economy without the worry about carbon dioxide pollution and global warming. The trouble with dihydrogen is that it is not easy to store and transport from the point of generation to the point of use. It takes the know-how of rocket engineers to store and transport liquid hydrogen. Compressed hydrogen gas is bulky and the cylinders are heavy. Other modes of hydrogen storage and transport suitable for the general population are needed and this is what motivated further research on ammonia borane.

Reversible hydrogen storage media have been sought for many decades. Much effort has been put into iron titanium hydride as a hydrogen storage medium, but the  $\text{LaNi}_5$  or Fe/Ti alloy is heavy and the tanks required for high-pressure storage are bulky, thick-walled, and heavy. The potential ability to store hydrogen in a lightweight fluid (instead of a solid) that is easy to regenerate has put the spotlight of energy research on ammonia borane and similar boron compounds. Ammonia borane has a hydrogen content of 19.6% by mass and most of that can be released when the chemical is decomposed [447, 448]. An entire chapter in a book on hydrogen storage is devoted to ammonia borane [449]. The fact that ammonia borane decomposes at moderate temperatures unfortunately eliminates it as a stable, storable rocket fuel, but opens new applications as a hydrogen storage medium. It must be emphasized that if any ammonia borane-type compound is to be used in rocket propellants or gas generators, it must be stable at room temperature and under tropical storage conditions. The current section only provides information on the preparation, properties, and safety

properties of ammonia borane and similar borazane compounds. These chemicals can be used in hydrogen gas generators (reversible or irreversible). The exothermic reaction leading to the release of dihydrogen can usually be initiated by means of an electrically heated nichrome wire. Once initiated, the reaction would propagate through the entire charge, it cannot be controlled, and it cannot deliver metered and varying amounts of hydrogen. It is with the application as a solid hydrogen gas generant in mind that the preparation and the properties of ammonia borane are discussed here in detail. The hydrogen may not only be used in combustion engines and fuel cells but may also be needed for chemical lasers (deuterium) or for inflation of weather or surveillance balloons at the battle front line.

Ammonia borane has received a lot of attention not as a rocket propellant, but as a potential method for hydrogen storage. At one time, it was touted as a benefit to the general population as a derivative of military/space activity in borane fuels dating back to the 1950s, just as the Teflon-coated frying pans were advertised as a spinoff from the space program in the 1960s. However, the dehydrogenation of ammonia borane is stepwise, non-reversible, and results in the formation of undesirable byproducts. Volatile byproducts will be carried out with the evolved hydrogen and may contaminate the hydrogen-using equipment. In a critical review of the flurry of ammonia borane activity, one must conclude that its potential as a reversible storage medium for dihydrogen was highly overrated and that an economic method of regeneration (rehydrogenation) of its decomposition products was never demonstrated [450]. A short section below summarizes the efforts to regenerate spent ammonia diborane (Section 6.6.4.3). Although ammonia borane is a promising hydrogen storage medium, the world's limited supply of boron minerals would be insufficient to allow it to become a widespread storage medium for all automobiles and to compete with gasoline in the future. Ammonia borane is a solid and it would be awkward to load it into the apparatus that generates hydrogen. If a chemical with the same hydrogen storage capability was available that was a liquid instead of a solid, the chances for acceptance into the hydrogen economy would be much better. Future applications of solid ammonia borane would be in small portable devices (fuel cells) where energy density is at a premium.

In looking at the various hydrides tested as hydrogen storage candidates, some hydrides release hydrogen at too low a temperature and are unstable at room temperature, whereas others require very high temperature that would require parasitic energy and long warm-up periods.

There are several reviews of the chemistry of ammonia borane and alkyl amine boranes that provide references for further study [449, 451–454]. Hydrazinoborane, which is discussed in one of the following sections, may offer similar hydrogen storage capability, similar to ammonia borane. It can also be used as a rocket propellant ingredient.

### 6.6.1 Preparation of Ammonia Borane

Ammonia borane can be prepared by reaction of lithium borohydride with ammonium salts in diethyl ether:

or by reaction of the DADB with ammonium chloride and a trace of excess ammonia [383, 455, 456]:

A more elegant method delivers the compound in a solution with diethyl ether [457]. In this synthesis,  $\text{NaBH}_4$  and ammonium sulfamate  $\text{NH}_4\text{NH}_2\text{SO}_3$ , under anhydrous conditions, are dissolved in liquid  $\text{NH}_3$  with vigorous stirring, diethyl ether is added, and the mixture is stirred continuously while it is allowed to warm. Near 273 K (0 °C) the reaction

begins to take place and continues for 3 to 4 h after the mixture reaches room temperature. The synthesis is completed by filtering the solution to remove the precipitate and distilling away the ether, leaving behind solid  $\text{BH}_3\text{NH}_3$ .

Another method used ammonium carbonate (carbamate) as the ammonium salt, giving a 80% yield of  $\text{BH}_3\text{NH}_3$  [458].

A one-pot synthesis of ammonia borane and trialkylamine-boranes starts with trimethyl borate, which is cheaper to obtain than sodium borohydride, yielding ammonia borane in 90% yield and >99% purity [459]. This method can also be applied to trialkylamine-boranes:

Ammonia promotes the synthesis of pure ammonia borane in excellent yields from sodium borohydride and ammonium sulfate in tetrahydrofuran under ambient conditions [460]. An examination of the influence of added ammonia revealed that it is incorporated into the product ammonia borane, contrary to its perceived function as a catalyst or a co-solvent.

In a simple, large-scale synthesis of ammonia borane from  $\text{NaBH}_4$  and  $(\text{NH}_4)_2\text{SO}_4$  at temperatures between 0 °C and room temperature in THF containing 5%  $\text{NH}_3$ , the presence of ammonia is critical for the reaction to proceed and allows the reaction at

high concentrations and ambient temperature without the need for anhydrous solvent or an inert atmosphere [461, 462]. The yield can be up to 92%.

Usually when working with boron hydrides and metal hydrides one would want to work under anhydrous conditions. Thus, it is highly unusual to learn that a trace of water can enhance the synthesis of ammonia borane. Ammonia borane has been synthesized in very high purity (>99%) from sodium borohydride and ammonium sulfate under ambient conditions in tetrahydrofuran (THF) at 1 M concentration using water as the promoter [463].

Ammonia borane can be prepared by simple displacement reactions that may be more economical than the methods used in the past [464]. Simple displacement reactions have been thwarted by the formation of the DADB, an ionic byproduct. Preparation of pure ammonia borane by displacement reactions with either ammonia with dimethylsulfide borane or ammonia with dimethylaniline borane in toluene at room temperature may be a promising alternative.

A closely related compound is diaminoborane  $\text{H}_2\text{NBH}\text{NH}_2$ , which was prepared by passing a stream of ammonia gas through molten ammonia borane in a pressure vessel at 398 K (125 °C) [457, 465]:

The DADB, dihydridodiammineboron (III) borohydride,  $[(\text{NH}_3)_2\text{BH}_2]^+[\text{BH}_4]^-$ , was synthesized by a metathesis reaction between the diammoniate of monochloroborane and potassium borohydride in liquid ammonia [466].  $^1\text{H}$  and  $^{11}\text{B}$  NMR spectra of the DADB helped to verify the structure of the molecule. The stability in THF was examined using variable-temperature  $^{11}\text{B}$  NMR spectroscopy.

### 6.6.2 Physical Properties of Ammonia Borane

Ammonia borane forms colorless crystals that have a density of  $0.78 \text{ g/cm}^3$  and melt at 377 K (104 °C) under decomposition. Other sources gave the density as  $0.73 \text{ g/cm}^3$ .

The heat of formation of solid ammonia borane is  $-174.2 \pm 5.8 \text{ kJ/mol}$  ( $-41.63 \pm 1.4 \text{ kcal/mol}$ ) and the heat of combustion is  $-1348.5 \pm 2.9 \text{ kJ/mol}$  ( $322.3 \pm 0.7 \text{ kcal/mol}$ ) [467].

The dipole moment of ammonia borane,  $\text{H}_3\text{NBH}_3$ , has been measured as 4.9 Debye units in dioxane solution [468] and 5.22 D in the dry state.

Ammonia borane is very soluble in liquid ammonia and this may be one of the methods by which ammonia borane will be transported and used as a hydrogen storage medium [469]. Ammonia borane can absorb ammonia to generate a series of liquid ammino complexes,  $\text{BH}_3\text{NH}_3 \cdot (\text{NH}_3)_n$ , after exposure to ammonia gas under the pressure range of 1 to 4 bar at 273 K (0 °C). Under an ammonia atmosphere, ammonia

borane reversibly absorbs up to at least six equivalents of  $\text{NH}_3$ . The strong classical hydrogen bond formed between the lone pair of  $\text{NH}_3$  and the  $-\text{NH}_3$  of ammonia borane is the driving force for the absorption of ammonia by ammonia borane. At 4 bar pressure, there were six moles of ammonia attached to each ammonia diborane molecule.

### 6.6.3 Molecular Structure of Ammonia Borane

The ammonia borane molecule structure is similar to that of ethane, with which it is isoelectronic. However, ammonia diborane is a solid and ethane is a gas at room temperature. The existence of the dihydrogen bonds largely explains the very different melting points of  $\text{BH}_3\text{NH}_3$  (383 K = 110 °C) and the isoelectronic compound ethane  $\text{CH}_3\text{CH}_3$  (92 K = -181 °C), as well as the higher volumetric hydrogen storage density of ammonia borane compared with ethane. Ammonia borane  $\text{H}_3\text{B}-\text{NH}_3$  is isoelectronic with ethane  $\text{H}_3\text{C}-\text{CH}_3$ , but it has very different properties owing to (1) the nitrogen and boron atoms (leading to a dipole moment), (2) the protic and hydridic hydrogens, and (3) the heteropolar dihydrogen bonding (rationalizing its solid state under ambient conditions). Ammonia diborane is expected to have a high dipole moment, as opposed to a dipole moment of zero for non-polar ethane.

The microwave spectra of nine isotopic species of ammonia borane with  $^{10}\text{B}$ ,  $^{11}\text{B}$ ,  $^1\text{H}$ ,  $^2\text{H}$  (= D),  $^{14}\text{N}$ , and  $^{15}\text{N}$  isotope substitution gave different sets of rotational constants, centrifugal distortion constants, dipole moments, torsional barriers, and molecular geometry [470]. The structural parameters of the ammonia borane molecule were:  $\text{B}-\text{N} = 1.6576(16) \text{ \AA}$ ,  $\text{B}-\text{H} = 1.2160(17) \text{ \AA}$ ,  $\text{N}-\text{H} = 1.0140(20) \text{ \AA}$ ,  $\angle\text{NBH} = 104.69(11)^\circ$ , and  $\angle\text{BNH} = 110.28(14)^\circ$ . The dipole moment was 5.216(17) Debye. The torsional barrier about the  $\text{B}-\text{N}$  bond was 2.047(9) kcal/mol for  $\text{H}_3^{11}\text{BND}_2\text{H}$  and 2.008(4) kcal/mol for  $\text{D}_2\text{H}^{11}\text{BNH}_3$ . It was not possible to determine, from the isotopic species studied, whether the staggered or eclipsed structure is the preferred geometry of the ground state.

The molecular structure of ammonia diborane at very high pressures under an atmosphere of hydrogen was investigated extensively because it was hoped that the low-pressure dehydrogenation of ammonia diborane would be reversible at high pressures, thus allowing a path to regenerate it as a hydrogen storage medium.

The effects of high pressures (up to 40 kbar) on dihydrogen-bonded  $\text{BH}_3\text{NH}_3$  molecular crystals were investigated using Raman spectroscopy in diamond and moissanite anvil cells [471]. The stretching mode frequencies of the  $\text{NH}_3$  proton donor groups exhibited moderate red shifts with increasing pressures, as found in many conventional hydrogen-bonded systems of weak to medium strength. The stretching modes corresponding to the  $\text{BH}_3$  proton acceptor group, on the other hand, showed large blue shifts with increasing pressure, which, however, were not related to the changes in the  $\text{N}-\text{H}\cdots\text{H}-\text{B}$  interactions. The  $\text{BH}_3\text{NH}_3$  crystals underwent a pressure-induced disorder-order phase transition around 8 kbar, which was facilitated by the presence of dihydrogen bonds.

The crystal structure of ammonia borane has been determined for the orthorhombic (at 90 K) and tetragonal (at 298 K) modifications using single-crystal XRD [472]. The orthorhombic structure (space group  $Pmn2_1$ ) agreed with a previously published neutron diffraction determination, whereas the tetragonal structure ( $I4mm$ ) exhibited halos of hydrogen atom occupancy around both the nitrogen and boron atoms. The bond angles to the regions of hydrogen occupancy were consistent with the expected tetrahedral geometry for  $\text{-BH}_3$  and  $\text{-NH}_3$  groups. A new model for bi-tetragonal  $\text{BH}_3\text{NH}_3$  was constructed, which accounted for the hydrogen disorder in the  $I4mm$  structure.

In ethane, the two halves of the molecule rotate freely around the C—C bond axis with only minor hindrances. In ammonia borane, the two halves do not rotate independently. The activation energies for rotations in low-temperature orthorhombic ammonia borane were analyzed and characterized in terms of electronic structure theory [473]. The barrier for independent  $\text{NH}_3$  rotation,  $E_a = 12.7$  kJ/mol, largely depends on the molecular conformational torsion in the solid-state geometry. The barrier for independent  $\text{BH}_3$  rotation,  $E_a = 38.3$  kJ/mol, results from the summation of the effect of molecular torsion and large repulsive intermolecular hydrogen-hydrogen interactions. However, a barrier of  $E_a = 31.1$  kJ/mol was calculated for internally correlated rotation with preserved molecular conformation. Analysis of the barrier heights and the corresponding rotational pathways showed that rotation of the  $\text{BH}_3$  group involves strongly correlated rotation of the  $\text{NH}_3$  end of the molecule.

Ammonia borane has three known structural phases in the temperature and pressure ranges 110–300 K and 0–1.5 GPa respectively. The boundaries between, and the ranges of stability of, these phases were located by *in situ* measurements of the thermal conductivity, whereas the actual structures in selected areas were identified using *in situ* Raman spectroscopy and XRD [474]. Below 0.6 GPa, reversible transitions involving only small hysteresis effects occurred between the room-temperature tetragonal plastic crystal  $I4mm$  phase and the low-temperature orthorhombic  $Pmn2_1$  phase. Transformations of the  $I4mm$  phase into the high-pressure orthorhombic  $Cmc2_1$  phase, occurring above 0.8 GPa, were associated with very large hysteresis effects, such that the reverse transition may occur at up to 0.5 GPa lower pressures. The thermal conductivity of the plastic crystal  $I4mm$  phase was about  $0.6 \text{ W m}^{-1} \text{ K}^{-1}$  and only weakly dependent on temperature, whereas the ordered orthorhombic phases had higher thermal conductivities limited by phonon-phonon scattering.

The effect of pressure on the low-temperature tetragonal ( $I4mm$ ) to orthorhombic ( $Pmn2_1$ ) phase transition of ammonia borane was investigated in a diamond anvil cell using Raman spectroscopy [475]. With applied pressure, the transition occurred at a higher temperature, which indicated that pressure enhances the ordering of the structure. Appearance of some of the characteristic Raman modes of the orthorhombic phase required undercooling of around  $\sim 15$  K below the transition, indicating the possible existence of an intermediate phase.

The phase transformation behavior of ammonia borane was examined at a low temperature (modified from room temperature down to 90 K) and high pressure (mod-

ified from ambient pressure to 9.5 GPa at room temperature and up to 15 GPa at 90 K) using a diamond anvil cell [476]. Ammonia borane showed four phase transitions in this pressure and temperature region. The phase transitions were indicated by the splitting of a peak and/or the appearance of a new peak in the Raman spectra as well as by the change of the pressure coefficient of the Raman modes. The phase boundaries between these phases were established during different cooling cycles. See also [477] and [478].

Raman spectroscopy studies indicated five transitions under compression up to 65 GPa at ambient temperature [479]. Diffraction experiments and theoretical studies demonstrated that three of these transitions were first-order phase transformations in the sequence of  $I4mm-Cmc2_1-P2_1$ -(different)  $P2_1$ , and two were iso-structural. A low-temperature phase ( $Pmn2_1$ ) and a high-temperature, high-pressure phase ( $Pmna$ ) were also recognized.

Under certain conditions at low temperatures, ammonia borane reverts to its ionic isomer, the DADB [480]. The structure of this compound was the object of debate for a significant period of time and was widely investigated in experiments using  $^{11}\text{B}$ -NMR and Raman studies. DADB is usually obtained as an X-ray amorphous white powder and appears in two modifications. DADB is stable up to 353 K (80 °C) and decomposes at 363 K (90 °C) with melting. It is soluble in liquid ammonia and is, in contrast to ammonia borane, not soluble in diethyl ether.

The diammoniate of diborane, dihydridodiammineboron (III) borohydride,  $[(\text{NH}_3)_2\text{BH}_2]^+[\text{BH}_4]^-$ , is formed from the room temperature decomposition of  $\text{NH}_4^+\text{BH}_4^-$ , via an  $\text{NH}_3\text{BH}_3$  intermediate [481]:

Its crystal structure has been determined and contains disordered  $\text{BH}_4^-$  ions in two distinct sites. Hydrogen release was similar to that from  $\text{NH}_3\text{BH}_3$  but with faster kinetics. Reaction of the DADB with ammonia in ether results in the formation of ammonia borane and hydrogen.

#### 6.6.4 Chemical Properties of Ammonia Borane

Ammonia borane is a white crystalline material that is relatively stable in air, although reports on its stability vary slightly. Unlike ionic hydrides, ammonia borane  $\text{H}_3\text{NBH}_3$  does not react violently with water. Aqueous solutions of ammonia borane decompose slowly at room temperature.

Ammonia borane is soluble in water and in many organic solvents. It is quite soluble (>5 mass-%) without reaction in EtOH, THF, diglyme, and triglyme; moderately (0.5–1 mass-%) soluble in  $\text{Et}_2\text{O}$  and dioxane; and poorly (<0.1 mass-%) soluble in toluene, benzene, or tetrachloromethane. Ammonia borane is soluble in water but slowly hydrolyzes at the rate of about 1%/day. The solubility of ammonia borane in water is high, 25 mass-% [482, 483]. Aqueous ammonia borane solutions are relatively

stable if kept under an inert gas atmosphere. In air the solution possesses much lower stability, which is believed to result from an increase in acidity in the solution due to the dissolution of  $\text{CO}_2$  [484]. Although the water solvent would need to be carried as unwanted ballast, ammonia borane solutions might be easier to accommodate in hydrogen-powered vehicles than solid ammonia borane. Hydrogen can be released by heating an aqueous ammonia borane solution to 353–408 K (80–135 °C) and 101–1379 kPa (14.7–200 psia) to release hydrogen by hydrothermolysis [485]. The hydrogen release temperature of ammonia borane solutions can be lowered by using transition metal catalysts [486].

#### 6.6.4.1 Thermal Decomposition of Ammonia Borane

The controlled deliberate decomposition of ammonia borane as a source of dihydrogen gas has been extensively investigated, in the solid, molten, and dissolved states. There are hundreds of publications dealing with the decomposition of ammonia borane as a source of hydrogen, and only a few of those have been referenced here. The hydrogen release from ammonia borane is a multi-step process.

As the dehydrogenation reaction is exothermic, the applied temperature is only needed to initiate the desired dehydrogenation process. The exothermicity of ammonia borane is a positive feature if fast hydrogen release of the complete hydrogen content is desired in a one-shot device as for a chemical laser. With large storage containers where only a small portion of the hydrogen is supposed to be extracted, the exothermicity poses a control problem. If one does not want to run the risk of a thermal run-away from an unintentional emission of the complete hydrogen content in the case of a malfunction of the control mechanism, the storage of ammonia borane in small compartments is inevitable, as in an automobile that is started and stopped. A possible alternative to the pyrolytic decomposition of solid ammonia borane is the decomposition in solution. The decomposition of ammonia borane in solution has the advantage of separating the decomposition zone from the storage area because of the improved transport of the stored material in liquid form. Better ammonia borane transport properties in the form of liquid solutions also allow the application of heterogeneous catalysts for the controlled decomposition of ammonia borane, as the reactants and products can be easily moved to or away from the catalyst.

Differential scanning calorimetry, TGA, and volumetric measurements have shown that solid ammonia borane is thermally decomposed in two reaction steps, each releasing one molecule of hydrogen per formula unit at different temperature levels [487]. Both decomposition steps are exothermic (Figure 24).

The stepwise evolution of hydrogen is visible in Figure 24 above, but it becomes more clearly visible if the test is repeated as a lower heating rate of 0.1 K/min. If the temperature is increased at a comparably high heating rate of 10 K/min, the hydrogen release sets in shortly after the melting point at 385 K (112 °C) and reaches

**Figure 24:** Heat flow and  $\text{H}_2$  release during the thermal decomposition of ammonia borane, heating rate 1 K/min. (Republished and modified from [488], with permission of ©2010 John Wiley & Sons Books; permission conveyed through Copyright Clearance Center Inc.)

a maximum at 403 K (130 °C). The second step, releasing another equivalent of molecular hydrogen, occurs in the range 423–473 K (150–200 °C). Completion of the first dehydrogenation step below the melting temperature is possible, albeit only slowly, at isothermal conditions of approximately 343–363 K (70–90 °C). The hydrogen release rate is strongly temperature dependent, at 363 K (90 °C) the release is completed after 4 h, whereas at 343 K (70 °C) it takes 40 h to achieve completion. One problem is the contamination of the released hydrogen gas by volatile products. FTIR analysis of the evolved gases from the thermolysis of ammonia borane complex has shown that monomeric aminoborane ( $\text{BH}_2\text{NH}_2$ ), borazine, and diborane is also produced. Another problem is the slow, sluggish response after a demand of hydrogen is signaled to the gas generator and the heat is turned on. If the material is heated to 363 K (90 °C), almost no hydrogen release is initially observed. Subsequently, the release rate increases slowly and then reaches its maximum only after 40 min. The induction period can be shortened by additives [489].

The decomposition of ammonia borane has been studied at low [490] and at very high pressures. The thermal decomposition of ammonia borane at up to 450 K and 600 bar has been studied by DSC and volumetric analysis of the released volatile decomposition products [491]. Above 360 K ammonia borane underwent an exothermic decomposition, which proceeds in two steps with rising temperature. The heat evolution and hydrogen release terminates near 430 K. The final amount of released hydrogen is approximately equal to 2 mol  $\text{H}_2$ /mol ammonia borane.

Stored under vacuum at room temperature, no significant hydrogen loss was reported for a period of over 2 months and its solubility in organic solvents remained unchanged [492]. In contrast, other reports of its storage in air indicated a slow hydrogen loss, presumably induced by humidity. Ammonia borane melts with hydrogen release, leading to a strong volume expansion by foaming. After some time of continued heating, the product solidifies. Reports on the melting point vary strongly from 377 to 383–389 K (104 to 110–116 °C) and all the way up to 397 K (124 °C; under hydrogen pressure). Impurities have a strong effect on lowering the melting point and storage stability.

A study of the thermal decomposition of ammonia borane by TGA, DTA, and decomposition product measurements showed vigorous decomposition with hydrogen evolution that began near 393 K (120 °C) and proceeded in stages as the temperature was increased to 473 K (200 °C), leaving a white residue [493]. The composition of the residue was approximately  $\text{BNH}_{2.1}$  after heating to 443 K (170 °C) and  $\text{BNH}_{(0.8-1.2)}$  after heating to 473 K (200 °C). There was some evidence for further slow hydrogen loss above that temperature. The swelling and foaming of decomposing ammonia borane makes DTA and TGA analyses difficult [494].

The thermal dehydrogenation of solid ammonia borane preferentially leads to polymeric products whereas the non-hydrolytic decomposition in solution results primarily in cyclic liquid compounds such as borazine, the BN analog to benzene. Intermediates in this reaction include monomeric aminoborane  $\text{H}_2\text{NBH}_2$ , which has a tendency to polymerize [495].

One equivalent of hydrogen gas was evolved from ammonia borane when it was heated above 343 K (70 °C). The initial stages of this process were examined using TGA/DSC, optical microscopy, and high temperature XRD [496]. Two exothermic events have been observed, the first of which took place without hydrogen evolution. During this stage, the sample lost its crystallinity and birefringence. The products were believed to be a more mobile form of  $\text{NH}_3\text{BH}_3$  and the diammoniate of diborane, dihydridodiammineboron (III) borohydride,  $[\text{NH}_3\text{BH}_2\text{NH}_3]^+[\text{BH}_4]^-$ . These products subsequently reacted in the second exothermic stage to generate hydrogen.

The ultimate product in the complete decomposition of ammonia borane is boron nitride [497]. Ammonia borane decomposition follows different reaction routes if the dehydrogenation occurs in a dissolved or solid state. A detailed study of ammonia borane dehydrogenation mechanism in diglyme and solid state showed that two main reaction pathways occur: one involves cyclization of monomers, which results in faster dehydrogenation at a lower temperature, whereas the other involves propagation to acyclic intermediates, which requires a higher temperature to carry out the cyclization step [498]. Ammonia borane dehydrogenation in the solid state was found to be initiated by B–N bond cleavage and not by direct dehydrogenation. It was found that diglyme plays a significant role in hindering B–N bond cleavage of ammonia borane, which facilitates the cyclization pathway.

Studies on ammonia borane decomposition have focused on relatively slow heating rates, showing that the mass lost because of decomposition increased with increasing heating rate. This trend has been confirmed, as mass loss continued to increase up to 50 K/min, the limit of most TGA/DSC instruments. Confined rapid thermolysis was used to examine the decomposition of ammonia borane under isothermal conditions [499–501]. FTIR spectroscopy and time-of-flight mass spectrometry were employed to identify the gaseous products, which included  $\text{H}_2$ ,  $\text{NH}_3$ ,  $\text{H}_2\text{NBH}_2$ , and cyclo- $\text{N}_3\text{B}_3\text{H}_6$ . The decomposition resulted in significant condensed-phase products as well, which were pressed into a KBr pellet and examined using FTIR spectroscopy. Condensable gas-phase products were collected from the stream of decomposition products, and FTIR spectroscopy showed that they have absorption bands similar to the polymeric species, indicating that the  $\text{H}_2\text{NBH}_2$  readily condenses out of the gas-phase products and polymerizes at low temperatures.

A Purdue University report is a mixture of reports on five different projects, but the section on pages 10 through 30 on confined rapid thermolysis of ammonia borane contains a thorough analysis of decomposition products of ammonia borane at different heating rates, supplemented by Molecular Dynamics Simulations calculations and many references to the relevant literature [502].

The decomposition of ammonia borane was studied using calorimetry, pressure measurements of evolved gases, and mass spectrometry methods [503]. It was shown that two competitive processes are taking place at 357 K, depending on the vapor pressure in the system. At atmospheric pressure, thermal decomposition with hydrogen evolution and polyamidoborane formation is the dominant process:

At low pressures (circa 4 mTorr) the major process is endothermic sublimation of ammonia borane:

At intermediate pressures both processes occur simultaneously. Enthalpies for the processes **(1)** and **(2)** have been determined by a drop-calorimetry method: for **(1)**  $\Delta H_{357} = -24.8 \pm 2.3 \text{ kJ/mol}$  and for **(2)**  $\Delta_{\text{sub}}H_{357} = 76.3 \pm 3.0 \text{ kJ/mol}$ . The activation energy for the process **(1)** within the range 327–351 K was  $94 \pm 11 \text{ kJ/mol}$  as determined by static pressure measurement. Based on the analysis of available thermodynamic characteristics, the standard enthalpy of formation  $\Delta H_f$  of solid ammonia borane was  $-133.4 \pm 5.2 \text{ kJ/mol}$  and for polyamidoborane a  $\Delta H_f$  of  $-156.7 \pm 5.8 \text{ kJ/mol}$  was recommended.

#### 6.6.4.2 Catalytic Decomposition of Ammonia Borane

The hydrogen release temperature of ammonia borane solutions can be lowered to more convenient temperatures by adding transition metal catalysts [486], dissolved Pt, Rh, and Pd salts injected into the ammonia borane solution [504], soluble rhodium, ruthenium, or platinum halogenide salts [505], salts of a weak base, and a strong acid such as  $\text{NH}_4\text{Cl}$  [506], or soluble rhodium or platinum halogenide salts [507].

#### 6.6.4.3 Regeneration of Ammonia Borane

The regeneration of exhausted ammonia borane residues may be mostly of interest for its use as a hydrogen storage medium and not so much for its use as a gas generant for lasers and balloon inflation. Nevertheless, this is part of ammonia borane chemistry and some of it is referenced here. The entire concept of hydrogen storage in ammonia borane hinges on an economic way to regenerate the spent residue. The ability to regenerate ammonia borane from its residues may affect its future availability from chemical suppliers as an ingredient in rocket propellants and gas generants.

To date, none of the proposed recycling schemes fulfills all of requirements for easy regeneration of the exhausted ammonia borane hydrogen storage medium. Ideally, the regeneration should proceed without additional energy requirements by pressurizing the exhausted medium with hydrogen gas at 10 MPa [508–510].

The spent fuel type derived from the release of more than two equivalents of  $\text{H}_2$  per molecule of ammonia borane (i.e., polyborazylene) can be converted back to ammonia borane nearly quantitatively by 24-h treatment with hydrazine in liquid ammonia at 313 K (40 °C) in a sealed pressure vessel [511, 512].

#### 6.6.5 Safety Properties of Ammonia Borane

An excellent survey of the methods of preparation, physical, chemical, and safety properties of ammonia borane and related alkylamine borane adducts is provided in [453]. This report, with 422 references, contains all the information one might need to safely handle ammonia borane, regardless if whether it is used as a rocket propellant or as a hydrogen storage medium.

#### 6.6.6 Applications of Ammonia Borane

Ammonia borane is a candidate medium for hydrogen storage and its properties and potential applications have been thoroughly investigated [488].

### 6.7 Ammonia Triborane

Another ammonia borane adduct that could be used as rocket propellant fuel or reversible hydrogen storage medium is ammonia triborane, also known as triborane(7), 3-amine-; triborane(7), ammoniate;  $\text{H}_3\text{NB}_3\text{H}_7$ , CAS RN [57808-44-3]. The melting point of ammonia triborane is 346 K (73 °C). Ammonia triborane is related

to the ammonium hydrotriborate salt  $[\text{NH}_4]^+[\text{B}_3\text{H}_8]^-$ , CAS RN [12447-26-6]. For its intended use as a hydrogen storage medium it turned out to be advantageous that it does not react with water in neutral or alkaline solutions and it is soluble in water. Ammonia triborane can be made from tetraborane by a series of reactions analogous to the preparation of ammonia borane from ammonia and diborane [513]. Ammonia triborane is a stable, white, crystalline solid when pure. Ammonia triborane is both soluble and stable in water, but upon the addition of acid or an appropriate transition metal catalyst it rapidly releases dihydrogen gas [514]. Ammonia triborane has a highly asymmetric structure in the solid state that results from intermolecular  $\text{N}-\text{H} + \cdots \text{H}-\text{B}$  dihydrogen bonding interactions [515, 516].

## 6.8 Hydrazine Borane

It is known that hydrazine reacts with pentaborane and other boranes in a highly exothermic, hypergolic reaction. So, in order to form adducts between hydrazine(s) and borane(s), one has to work in dilution with an inert solvent and provide cooling.

Hydrazine borane, also called hydrazine borane 1:1, borine hydrazine, hydrazine monoborane,  $\text{BH}_3 \cdot \text{N}_2\text{H}_4$ , CAS RN [14931-40-9], is a potential rocket propellant fuel and a source of dihydrogen for other energy conversion applications such as fuel cells. In parallel with the skyrocketing number of publications on ammonia borane as a hydrogen storage medium, the hydrazine boranes have also received recent attention, resulting in hundreds of publications. We are not interested in storage of hydrogen for non-rocket applications, which is the main topic of many publications on hydrazine borane and hydrazine bisborane. These publications are referenced here only because they provide information on the physical and chemical properties of these compounds. For their use as hydrogen storage media, the reversibility of the hydrogen release and hydrogen loading (regeneration) process has yet to be demonstrated. Once these compounds become available in larger quantities, they may even be used in rocket propellants or in hydrogen gas generators for chemical lasers. If ammonia borane, hydrazine borane, or hydrazine bisborane should evolve as a preferred hydrogen storage medium in the future, one can honestly claim that both building blocks of this hydrogen storage material have benefited substantially from a wealth of know-how that originated with their proposed or actual use as rocket propellants. Government-sponsored research into boranes and hydrazines in the 1950s, mostly aimed at propulsion for weapons, has now opened up an entire new field of chemistry for civilian uses.

### 6.8.1 Preparation of Hydrazine Borane

Hydrazine borane,  $\text{BH}_3 \cdot \text{N}_2\text{H}_4$ , can be made by reacting hydrazinium(2+) sulfate or hydrazinium(1+) chloride with sodium boranate  $\text{NaBH}_4$  [517–519].

Hydrazine borane,  $\text{N}_2\text{H}_4\text{BH}_3$ , stores 15.4 mass-% of hydrogen in hydridic and protic forms, and the challenge is to release  $\text{H}_2$  with maximum efficiency, if possible,

releasing all hydrogen stored in the material [520]. Hydrazine borane can be made by a two-step synthesis (salt metathesis and solvent extraction-drying) with a yield of about 80% and a purity of 99.6%.  $\text{N}_2\text{H}_4\text{BH}_3$  was characterized by NMR, IR, XRD, TGA, and DSC, its stability in dioxane and water was determined, and its thermolysis byproducts were characterized.

### 6.8.2 Physical Properties of Hydrazine Borane

Hydrazine borane has an enthalpy of formation of  $-975\text{ kJ/kg}$  ( $-233\text{ kcal/kg}$ ) and a density of  $0.95\text{ g/cm}^3$ . Hydrazine borane on heating decomposes partially to hydrazine bisborane, hydrazine diborane,  $\text{B}_2\text{H}_6\text{N}_2$ ,  $\text{H}_2\text{BNHNHBH}_2$ , CAS RN [13730-91-1], which exists mostly in a polymeric form and on further heating releases more dihydrogen gas (see Section 6.9 Hydrazine Bisborane).

Stable, solid adducts, which can be used in solid rocket propellants, are formed between hydrazine or alkylhydrazines and diborane, pentaborane, or decaborane [521]. The heat of combustion of  $\text{BH}_3\bullet\text{N}_2\text{H}_4$  is  $1644\text{ kJ/mol}$  ( $393\text{ kcal/mol}$ ).

Single-crystal XRD data showed that  $\text{BH}_3\bullet\text{N}_2\text{H}_4$ , m.p. =  $334\text{ K}$  ( $61^\circ\text{C}$ ), prepared in 70–75% yield from  $\text{NaBH}_4$  and  $(\text{N}_2\text{H}_5)_2\text{SO}_4$  in dioxane at  $303\text{--}343\text{ K}$  ( $30\text{--}70^\circ\text{C}$ ), is rhombic,  $a = 13.05\text{ \AA}$ ,  $b = 5.12\text{ \AA}$ ,  $c = 9.55\text{ \AA}$ ,  $Z = 8$ ,  $\rho_{25^\circ\text{C}} = 0.9475\text{ g/cm}^3$ , space group  $D102h\text{-Pccn}$  [522]. The observed frequencies in the IR spectra of  $\text{BH}_3\bullet\text{NH}_3$  and solid and liquid  $\text{BH}_3\bullet\text{N}_2\text{H}_4$  were assigned to molecular vibrations. The dipole moment of  $\text{BH}_3\bullet\text{N}_2\text{H}_4$ ,  $4.18\text{ D}$  was consistent with a largely *trans* form of the  $\text{N}_2\text{H}_4$  component. Data on dipole moment and molecular mass in dioxane showed that with increasing concentration,  $\text{BH}_3\bullet\text{N}_2\text{H}_4$  is increasingly associated.

An X-ray structural study has been made of crystals of borine hydrazine,  $\text{BH}_3\bullet\text{N}_2\text{H}_4$  [523]. Computation of the structure was carried out in parallel by two methods: a modified Monte Carlo method and Patterson function projections. The coordinates of the three atoms B, N1, and N2 were determined in both cases. The boron atoms and the nitrogen atoms closest to it have a tetrahedral valence configuration, the tetrahedra being arranged in *gauche* form. The length of the B–N bond was  $1.56 \pm 0.01\text{ \AA}$ . The crystal parameters were  $a = 9.53 \pm 0.07\text{ \AA}$ ;  $b = 5.12 \pm 0.06\text{ \AA}$ ;  $c = 13.01 \pm 0.08\text{ \AA}$ ; and  $\rho = 0.968\text{ g/cm}^3$ .

The electronic characteristics of the dative N–B bond in three Lewis acid-base adducts, hydrazine borane, hydrazine bisborane, and ammonia trifluoroborane, were analyzed using an approach combining experimental electron density determination with a broad variety of theoretical computations [524]. The main electronic effect of the formation of the Lewis acid-base adducts and of the crystallization is an increase in the charge separation within the ammonia/hydrazine fragments, which is supported by all investigated bond and atom properties. The nature of the dative N–B bond was found to be mainly electrostatic, but with a substantial contribution of covalency.

The structural behavior of hydrazine borane under mechanical stimulus was examined by synchrotron high-pressure XRD [525]. It was shown that hydrazine borane

undergoes a gradual pressure-induced decrease in its unit cell dimensions. The process is reversible when the applied pressure is released. The compressibility of this material was relatively low (high bulk modulus) and highly anisotropic. The mechanical behavior of hydrazine borane correlated with the pressure-induced changes of its crystal structure in terms of intra- and intermolecular bond lengths and angle parameters.

### 6.8.3 Chemical Properties of Hydrazine Borane

Unstable  $(\text{BH}_3 \bullet \text{N}_2\text{H}_5)_2\text{SO}_4$  and  $\text{BH}_3 \bullet \text{N}_2\text{H}_5\text{Cl}$  salts were obtained from solutions of hydrazine borane and the respective strong mineral acids in dioxane or THF [522]. Hydrazine borane forms salts with alkali metals, which release their hydrogen more readily than the parent compound [526, 527]. A clear correlation between sizes of metal cations in hydrazinoboranes and their corresponding melting and dehydrogenation temperatures was found, dependent on the melting temperature. Upon approaching the melting points, alkali metal hydrazinoboranes dehydrogenate rapidly in the first step, giving rise to the formation of intermediates that include  $\text{N}_2\text{BH}_2$ ,  $\text{N}_2\text{BH}$ , and  $\text{NBH}_3$  species.

Hydrazine borane ( $\text{N}_2\text{H}_4\text{BH}_3$ ) with a gravimetric hydrogen storage capacity of 15.4% can be used for the storage of hydrogen. Pyrolysis studies *in vacuo* over the temperature range 343–473 K (70–200 °C) showed that with release of some  $\text{N}_2\text{H}_4$  and, relatively rapidly, 1 mol of  $\text{H}_2$  per mol of hydrazine borane, a solid residue of variable composition resulted from which crystalline  $(\text{BH}_2\text{NH})_n$  was isolated [522].  $(\text{BH}_2\text{NH})_n$  resisted attack by  $\text{H}_2\text{O}$  or aqueous acids and probably has a polymeric structure composed of condensed six-membered rings; the N–N link is retained. At 473 K (200 °C),  $(\text{BH}_2\text{NH})_n$  slowly lost an additional  $\text{H}_2$  per mol of  $\text{BH}_3 \bullet \text{N}_2\text{H}_4$  to give an amorphous,  $\text{H}_2\text{O}$ -sensitive product of approximate composition  $(\text{HBN})_n$ . Loss of the second  $\text{H}_2$  from  $\text{BH}_3 \bullet \text{N}_2\text{H}_4$  occurred more rapidly if the initial decomposition products were not separated and led to unidentified, volatile, sometimes **explosive** products, which still had N–N bonds.

Metal-catalyzed hydrolysis of hydrazine borane at room temperature quickly released dihydrogen gas [528]. Among the catalyst systems tested, rhodium(III) chloride was found to provide the best catalytic activity. In the presence of dissolved rhodium(III) chloride, the aqueous solution of hydrazine borane underwent fast hydrolysis to release nearly 3.0 equivalents of  $\text{H}_2$  at room temperature. The reaction between hydrazine borane and water proceeded almost in stoichiometric proportion indicating that efficient hydrogen generation can be achieved even from highly concentrated solutions of hydrazine borane or in the solid state when water is added to the solid hydrazine borane.

Both hydrazine borane and ammonia borane have been evaluated as storage media for dihydrogen. The hydrogen release by hydrolysis of hydrazine borane can be catalyzed by rhodium nanoparticles supported on hydroxyapatite [529].

The hydrogen storage capabilities of hydrazine borane can be improved by adding an equimolar amount of lithium hydride [530]. The resulting mixture contains 14.8 mass-% hydrogen. The hydrogen release behavior of both the pure hydrazine borane and the LiH mixture showed hydrogen release rates at a reasonable operating temperature range of 373–523 K (100–150 °C). Similar improvements were observed with sodium hydride or potassium hydride instead of lithium hydride added to hydrazine borane [527]. Alkali metal hydrazidotrihydridoborates dehydrogenated rapidly in the first step with the formation of intermediates that contained  $\text{N}_2\text{BH}_2$ ,  $\text{N}_2\text{BH}$ , and  $\text{NBH}_3$  species. Further increasing temperature lead to the release of additional  $\text{H}_2$  and the formation of  $\text{N}_2\text{BH}$  species. Compared with bare  $\text{N}_2\text{H}_4\text{BH}_3$ , the alkali-metal-substituted hydrazidotrihydridoborates demonstrated significantly improved dehydrogenation behavior with no  $\text{N}_2\text{H}_4$  emission and greatly suppressed  $\text{NH}_3$  release. The hydrogen release temperatures of the potassium salt were then compared with the hydrogen release temperatures of the magnesium, calcium, and aluminum salts. Hydrazine borane  $\text{N}_2\text{H}_4\text{BH}_3$  can be destabilized by the addition of  $\text{MH}_x$  ( $x = 2, 3$ ;  $\text{M} = \text{Mg}, \text{Ca}, \text{Al}$ ), forming salts with better dehydrogenation properties [531]. In comparison with bare  $\text{N}_2\text{H}_4\text{BH}_3$ ,  $\text{MgH}_2$  had a catalytic effect;  $\text{CaH}_2$  strongly destabilized  $\text{N}_2\text{H}_4\text{BH}_3$ ; and unstable  $\text{AlH}_3$  can destabilize  $\text{N}_2\text{H}_4\text{BH}_3$  under heating. The most efficient salt was  $\text{CaH}_2 \cdot \text{N}_2\text{H}_4\text{BH}_3$ .

It was found that hydrazine borane and ammonia borane (mol ratio 1:1) destabilize each other [532]. The mixture can eventually be stabilized into a useful hydrogen storage material, which dehydrogenates in steps at temperatures up to 573 K (300 °C) to form boron nitride. Though stable at 293–298 K (20–25 °C), the mixture melted at ~303 K (~30 °C) and then underwent significant decomposition, with desorption of dihydrogen and hydrazine from 340 K (67 °C) on. Also, some dihydrogen was “explosively” liberated at around 363 K (90 °C). This was explained by the fact that the presence of hydrazine borane disrupts the  $\text{H}\delta + \cdots \text{H}\delta$  network of ammonia borane, and vice versa. The mixture is then much less stable than the borane adducts by themselves.

The presence of one mol of an alkaline borohydride ( $\text{LiBH}_4$  or  $\text{NaBH}_4$ ) per four mols of hydrazine borane  $\text{N}_2\text{H}_4 \cdot \text{BH}_3$  effectively destabilized  $\text{N}_2\text{H}_4 \cdot \text{BH}_3$ , which is then able to liberate dihydrogen as soon as it is heated to 323 K (50 °C) [533]. Upon heating up to 573 K (300 °C) at 5 °C/min, this mixture released 12.1 mol of dihydrogen (dehydrogenation extent of 76%) and 1.1 mol of  $\text{N}_2\text{H}_4$ . It may be possible to recycle and re-hydrate the solid residue of polyborazylene- and/or boron nitride-like materials.

The thermolytic dehydrogenation of hydrazine borane should be avoided because of the evolution of significant amounts of hydrazine and the formation of a shock-sensitive solid residue upon heating at >573 K (>300 °C) [534]. The alkali hydrazinidoboranes, obtained by reaction of hydrazine borane with alkali metal hydrides, would be more suitable to thermolytic dehydrogenation, with improved properties in comparison to the parent borane.

Hydrazinoboranes are of interest as sources of hydrogen for inflation of balloons and as rocket propellants. Their analysis is a difficult task, as simple iodometric titra-

tion would not only give the hydrazino group content, but to a varying extent some of the iodate would be consumed by the reducing properties of the borohydride. Simple gasometric analysis of the dinitrogen gas evolved by reaction of the BNH compound with iodate in aqueous solution does not work either, as the boron hydride develops some dihydrogen and would result in high nitrogen readings. A modified gasometric method for these BNH compounds reacts the sample with iodate solution and passes the  $N_2/H_2$  gas mixture over heated copper(II) oxide to remove dihydrogen [535]. A slow purge of carbon dioxide sweeps the gas into a gasometer (“nitrometer,” “azotometer”) filled with strong caustic where all the  $CO_2$  is absorbed.

## 6.9 Hydrazine Bisborane

### 6.9.1 Preparation of Hydrazine Bisborane

Hydrazine borane on heating decomposes partially to hydrazine bisborane,  $H_2BNHNHBH_2$ , CAS RN [13730-91-1], which exists mostly in a polymeric form and on further heating releases more dihydrogen gas [518, 536, 537].

### 6.9.2 Physical Properties of Hydrazine Bisborane

There is a discrepancy among the several values of the enthalpy of formation for hydrazine bisborane,  $B_2H_6 \bullet N_2H_4$ , with a molecular mass of 59.736 g/mol (16.7403 mol/kg). One source reported a heat of formation of  $-84.11 \text{ kJ/mol} = -1408 \text{ kJ/kg}$  ( $-20.10 \text{ kcal/mol} = -336.6 \text{ kcal/kg}$ ) and a density of  $0.94 \text{ g/cm}^3$ . Other sources gave a heat of formation of  $-125 \pm 21 \text{ kJ/mol} = -30 \pm 5 \text{ kcal/mol}$ .

The standard enthalpies of formation of hydrazine borane and hydrazine bisborane were obtained from a calorimetric study of the combustion of these compounds [538]. The  $\Delta H_f^\circ$  for solid  $N_2H_4BH_3$  and  $N_2H_4(BH_3)_2$  are  $-42.7 \pm 4.2 \text{ kJ/mol}$  ( $-10.2 \pm 1.0 \text{ kcal/mol}$ ) and  $-126.8 \pm 4.6 \text{ kJ/mol}$  ( $-30.3 \pm 1.1 \text{ kcal/mol}$ ) respectively.

The heat of combustion of crystalline  $(H_3B)_2N_2H_4$  was determined at 298 K (25 °C) and measured as  $2668 \pm 2.1 \text{ kJ/mol}$  ( $637.8 \pm 0.5 \text{ kcal/mol}$ ). Using this value and the  $\Delta H_f^\circ$ <sup>298.15</sup> of the combustion product, crystalline  $H_3BO_3$  ( $-261.71 \pm 0.31 \text{ kcal/mol}$ ), the standard heat formation of crystalline  $(H_3B)_2N_2H_4$  was calculated to be  $-22.2 \pm 0.8 \text{ kcal/mol}$  [539].

A lithium salt of hydrazine bisborane,  $LiNH(BH_3)NH_2BH_3$  can be synthesized via the reaction between hydrazine bisborane and BuLi in ether solution [540].  $^{11}\text{B}$  NMR and FTIR spectroscopy indicated a new structure, in which one of the N—H bonds is replaced by an N—Li bond. The XRD pattern of the product indicated the formation of a new crystal structure. This compound released  $H_2$  at 399 to 443 K (126 to 170 °C) with satisfactory purity and exhibited superior hydrogen storage properties compared with hydrazine bisborane. DSC measurements indicated that the dehydrogenation reaction of this compound was less exothermic than that of hydrazine bisborane.

### 6.9.3 Decomposition of Hydrazine Bisborane

Hydrazine bisborane is not stable in water, and is even less stable in alkaline aqueous solutions. Not only solid hydrazine bisborane [541] but also aqueous hydrazine bisborane solutions have been considered as a hydrogen storage medium [542]. The use of a metal-based catalyst accelerated the hydrolysis of the  $\text{BH}_3$  groups, but a bimetallic NiPt catalyst was more active, also being able to decompose the  $\text{N}_2\text{H}_4$  moiety. The best hydrogen evolution rate was at 343 K (70 °C) in alkaline solutions. However, the dehydrogenation was not complete, reaching a limit of only 80% of conversion.

Hydrazine bisborane contains two borine  $\text{BH}_3$  units per hydrazine molecule [543]. The hydrogen released by decomposition of hydrazine bisborane was shown to have a very high purity of >99%. The activation energy of the first-step dehydrogenation of hydrazine bisborane is 106.4 kJ/mol. Hydrazine bisborane also forms salts with lithium hydride that have a low hydrogen desorption temperature of 399 K (126 °C) [540].

Kinetics and mechanism of the thermal decomposition of hydrazine bisborane were determined by a manometric method using mass and IR spectrometry and thin-layer chromatography [544]. The decomposition proceeded according to a molecular mechanism and was first order, with a rate constant of  $k = 6.34 \times 10^7 \exp[-(24.1 \pm 0.5)/RT] \text{ s}^{-1}$ . Addition of  $\text{H}_3\text{B} \cdot \text{NH}_2\text{NH}_2$  accelerated the decomposition process.

Hydrazine bisborane has a relatively low dehydrogenation temperature (~100 °C), without generation of any unwanted gaseous products such as ammonia and diborane, and the released hydrogen had a very high purity of >99% [543]. The activation energy of the first-step dehydrogenation of hydrazine bisborane was calculated to be 106.4 kJ/mol using Kissinger's method. Based on  $^{11}\text{B}$  NMR and FTIR analysis of the products, the thermal decomposition of hydrazine bisborane produced  $[\text{HBN}_2\text{BH}]_2$  dimers.

The apparent activation energies of the first step for hydrazine bisborane and  $\text{NiCl}_2$ -doped hydrazine bisborane were 143.2 and 60.7 kJ/mol respectively [545]. DSC results showed that the addition of  $\text{NiCl}_2$  did not affect the enthalpy change of hydrazine bisborane dehydrogenation.

Experimental and computational methods were used to characterize hydrazine bisborane  $\text{N}_2\text{H}_4(\text{BH}_3)_2$  as a hydrogen storage medium, including XRD, NMR, FTIR, Raman, TGA, and DSC [546]. It was concluded that  $\text{N}_2\text{H}_4(\text{BH}_3)_2$  has the potential to be used as a hydrogen storage medium, assuming that both thermolytic and hydrolytic dehydrogenations were applied. In solid-state chemical hydrogen storage, it cannot be used because of the risk of explosions during dehydrogenation.

Borane compounds that are also being considered as reversible hydrogen storage media are hypergolic, with WFNA as the oxidizer [547]. When dissolved in ionic liquids, the borane solutions exhibited ignition delay times that were shorter than those of many known hypergolic ionic liquids.

## 7 Other Boron-Nitrogen Compounds

### 7.1 Alkylborane Alkylamine Adducts

Triethylborane is commercially available in the form of adducts with 1,3-diaminopropane or triethylenediamine.

### 7.2 Alkylborane Hydrazine Adducts

Trimethylborane forms Lewis adducts with hydrazine [548].

### 7.3 Aminoboranes

Aminoborane,  $\text{H}_2\text{NBH}_2$ , which has a tendency to polymerize, forms during the thermolysis of ammonia borane. The monomeric aminoborane is unstable at room temperature, oligomerizing to form a non-volatile white solid residue of poly(aminoboranes). Heating of poly(aminoboranes) releases dihydrogen and the ultimate product is boron nitride, which is difficult to convert back to ammonia borane if one wants to operate a hydrogen storage cycle [495]. There is a group of alkylaminoboranes where hydrogens on the nitrogen or the boron or both on nitrogen and boron are replaced by alkyl groups. These would be potential hypergolic fuels with a wide range of oxidizers. One example is dimethyl aminodimethylborane,  $(\text{H}_3\text{C})_2\text{N}-\text{B}(\text{CH}_3)_2$ , which is a liquid that freezes at 180.6 K ( $-92.5^\circ\text{C}$ ) and boils at 338 K ( $65^\circ\text{C}$ ).

### 7.4 Alkylamine-Borane Lewis Adducts

There are numerous adducts of the type  $\text{R}_{3-n}\text{H}_n\text{NBH}_3$  or  $\text{R}_{3-n}\text{H}_n\text{NBR}_3$  with  $n = 0, 1, 2$  that have acceptable properties as hypergolic fuels with WFNA or red fuming nitric acid (RFNA).

$\text{BH}_3$ -amine and  $\text{B}(\text{CH}_3)_3$ -amine adducts were investigated as potential additives for hypergolic rocket propellant combinations [549]. The investigation included the calculation of predicted properties for a variety of known and notional adducts. Property predictions were based on results from quantum chemistry methods. Predicted gas-phase properties included B–N bond dissociation energies and enthalpies of formation at 298 K [ $\Delta H_f^{298}(\text{G})$ ]. Predicted condensed-phase properties included enthalpies of sublimation, enthalpies of formation at 298 K [ $\Delta H_f^{298}(\text{S})$ ], and densities. The measured enthalpy of formation of trimethylamine borane in the gas phase was  $-85 \text{ kJ/mol}$  ( $-20.3 \text{ kcal/mol}$ ) and the predicted enthalpy of formation was  $-77 \text{ kJ/mol}$

(−18.4 kcal/mol). The measured enthalpy of formation of trimethylamine borane solid phase was −141 kJ/mol (−33.81 kcal/mol). The measured enthalpy of formation of trimethylamine trimethylborane in the gas phase was −220 kJ/mol (−52.6 kcal/mol) and the predicted calculated number was −212 kJ/mol (−50.6 kcal/mol). The measured enthalpy of formation of trimethylamine trimethylborane in the solid phase was −279 kJ/mol (−66.6 kcal/mol) and the predicted calculated number was −272 kJ/mol (−65.0 kcal/mol). The  $\Delta H_f^{298}(\text{S})$  estimates were then used as input for thermochemical code-based calculations of the specific impulse that adducts could potentially generate when combined with IRFNA. Several  $\text{BH}_3$ -amine adducts warrant further investigation as additives for liquid/gel hypergols or for solid fuels for hybrid concepts.

An alkylamine borane adduct of unusual inertness in air and thermal stability is bisborane-triethylenediamine, which was non-volatile and did not melt at temperatures up to 623 K (350 °C) [550]. Lewis adduct formation of amines with borane converts them to hypergols (if they were not hypergolic to start with) or decreases their ignition delays (if they already had some hypergolicity) multifold with WFNA or RFNA as the oxidizer. With consistently low ignition delays, amine boranes represent a class of compounds that can be promising alternatives to hydrazines as bipropellant fuels. A structure-hypergolicity relationship study revealed the necessary features for a low ignition delay [551].

Solid amine boranes, in particular, ethylenediamine bisborane, can be used as high-performance hypergolic hybrid rocket fuels and their combustion behavior in a hypergolic hybrid combustor has been investigated [552, 553]. The addition of a borane adduct to an amine fuel tends to reduce the ignition delay with WFNA by up to an order of magnitude.

The (mono-, di-, tri-)methylamine-borane adducts are solids like real salts and their crystalline structures are known [554]. The structures of methylamine borane,  $\text{MeH}_2\text{N}\cdot\text{BH}_3$  and dimethylamine borane,  $\text{Me}_2\text{HN}\cdot\text{BH}_3$ , have been investigated by gas-phase electron diffraction and quantum chemical calculations. The crystal structures have been determined for methylamine, dimethylamine, and trimethylamine borane,  $\text{Me}_n\text{H}_{3-n}\text{N}\cdot\text{BH}_3$  ( $n=1-3$ ), by XRD and revealed the intermolecular interactions and, particularly, the  $\text{N}-\text{H}\cdots\text{H}-\text{B}$  dihydrogen bonding in the cases where  $n=1$  or 2. The enthalpy of formation of solid trimethylamine borane is −146 kJ/mol (−34.8 kcal/mol). The ammonia-trimethylborane adduct melts at 347 K (74 °C), and its enthalpy of formation in the solid state is −286 kJ/mol (−68.3 kcal/mol). The methylamine-trimethylborane adduct melts at 300 K (27 °C) and boils at 420 K (147 °C) with dissociation. The trimethylamine-trimethylborane adduct melts at 401 K (128 °C) whereas the trimethylamine-triethylborane adduct is a liquid and freezes at 227 K (−46 °C).

The adduct of methylamine and diborane,  $\text{H}_3\text{CNH}_2\cdot\text{BH}_3$  is a solid and melts at 331 K (58 °C) [383]. It is soluble in diethyl ether or dioxane.

Instead of preparing the Lewis adducts directly from diborane and free amines, the adducts *N*-dimethylaminoborane, trimethylamine-borane, and *N*-tri-

methylborazole can be prepared more economically from lithium borohydride and the (bi, tri)methylammonium chloride [555].

It was hoped that forming addition compounds of diborane with alkylamines would reduce the vapor pressure and the toxicity of diborane. A comparison of the acute toxicity of dimethylamine-borane with the acute toxicity of pyridine-borane and trimethylamine-borane showed that, on a weight basis, the order of decreasing toxicity would be dimethylamine-borane > pyridine-borane > trimethylamine-borane [556]. However, when expressed in terms of mg B/kg, the LD50 values formed two distinct groups, still more toxic than hydrocarbon fuels such as RP-1.

Selected amine boranes (e.g., trimethylamine cyanoborane, *N*-methylmorpholine cyanoborane, and the base-boronated 2'-deoxynucleosides) are under evaluation as pharmaceutical drugs and have anti-inflammatory, analgesic, anti-arthritis, and anti-osteoporotic activities. Triethylamine borane has a short ignition delay with WFNA, but a high melting point. Methanol, triethylamine, and ammonium tetraphenylborate have been evaluated as freezing point depressants for triethylamine borane [557].

### 7.5 Ammonia-(Dinitramido)Boranes

Ammonia-(dinitramido)boranes,  $\text{H}_3\text{NH}_2\text{BN}(\text{NO}_2)_2$ , are members of a new class of chemicals that are potentially useful as rocket propellants. Two ammonia-(dinitramido)boranes were synthesized by the reaction of dinitroamine with ammonia borane [558]. Ammonia-mono(dinitramido)borane is a perfectly oxygen-balanced high-energy density material composed of an ammonia-BH<sub>2</sub> fuel group and a strongly oxidizing dinitramido ligand. Although it is thermally not stable enough for practical applications, its heat of explosion is 916 kJ/mol (219 kcal/mol) and its predicted specific impulse as a solid rocket propellant would be 333 s. Its predicted performance as an explosive matches that of pentaerythritol tetranitrate and significantly exceeds that of TNT. Its structure was established using XRD and vibrational and multi-nuclear NMR spectroscopy (Figure 25).

Figure 25: Molecular structure of ammonia-dinitramidoborane.

# Boron

Elemental boron has been tested as a fuel in solid propellants, ram-air rockets, gelled liquid fuel slurries, and hybrid fuel grains. Elemental boron is a solid, so it should not really be included in a volume entitled *Encyclopedia of Liquid Fuels*. However, we assume here that the boron is used as a finely divided powder suspended in a kerosene slurry, making it a liquid fuel. There is special interest in nanosize particles of boron that remain in suspension without the aid of a gelling agent. For general information on elemental boron, see [1] and [2].

## 1 Preparation of Elemental Boron

Amorphous boron solidifies from a melt in the shape of black, glass-like shards or is obtained in the form of a brown powder from thermite processes. Elemental boron can be made by a self-propagating high-temperature synthesis (SHS) thermite (*magnesiothermic*) process:

but the raw product is always contaminated with magnesium or carbon. Those contaminants do not interfere with the intended use of boron in rocket propellants or igniter pyrotechnic mixtures. Calculations showed that the adiabatic combustion temperature of the  $\text{B}_2\text{O}_3/\text{Mg}$  reaction system was 2604 K. This high thermite temperature causes unwanted coagulation of the boron particles that formed. Smaller particle sizes can be obtained if the reaction is conducted at lower temperatures in a diluent molten salt bath [3]. The diluent salt most often used is simple rock salt, NaCl. Nanosized amorphous boron powders were synthesized by an active dilution self-propagating high-temperature synthesis (SHS) method at moderate temperatures ranging from 973 to 1023 K (700–850 °C) in an SHS furnace using Mg,  $\text{B}_2\text{O}_3$ , and  $\text{KBH}_4$  as raw materials [4].

Amorphous boron nanoparticles can be synthesized by heating a  $\text{B}_2\text{O}_3 + 3\text{Mg} + n\text{NaCl}$  (where  $n$  is the number of moles of NaCl used as diluent) exothermic mixture in a laboratory oven at 1073 K (800 °C) under argon flow [5]. NaCl was used as an inert material to decrease the maximum combustion temperature of the reaction mixture when it was self-ignited after the melting of Mg at 923 K (650 °C). The sizes of the boron nanoparticles extracted from the final product by acid leaching ranged between 30 and 300 nm for  $n$  values ranging from 1 to 5.

Boron powders with sub-micron sizes can be prepared by salt-assisted combustion synthesis in an argon atmosphere using  $\text{B}_2\text{O}_3$  and Mg powders as starting materials and NaCl as diluent [6]. The average size of the boron particles decreased and

their dispersibility improved after starting to use diluent NaCl. The purity of samples prepared by adding 50% NaCl was the highest, 96% B, and the average particle size was within 0.4–0.8  $\mu\text{m}$ .

Pure boron can be obtained by reduction of boron trichloride with hydrogen or by thermal decomposition of diborane.

A review presented four main techniques for the preparation of elemental boron: molten salt electrolysis, metallic reduction, hydrogen reduction, and controlled decomposition of boron compounds [7]. Electrowinning of boron is conducted in molten salt systems. Four types of hydrogen reduction of boron compounds are in use. For chemical vapor deposition processes used in semiconductor and superconductor production, the purity, conversion rate, morphology, and deposition rate of the produced boron are major concerns. Like hydrogen reduction, decomposition of boron compounds can be used to produce high-purity and ultra-fine boron, but the high cost and severe reaction conditions will limit any applications of this process on a large scale. See also [8, 9].

Boron powders with high purity, a small particle size, and a narrow particle size distribution are preferred in high-tech industrial fields, but purity is not so critical if they are to be burned in a rocket propellant. Boron powder can be purified by leaching with acid [10].

In order to achieve complete combustion of boron or metal particles in an air-breathing or a rocket combustion chamber, the target during the past decades has been to produce boron (and aluminum) in smaller and smaller particle sizes. The production of nanoboron poses unique challenges, but both boron and aluminum in various nanoparticle sizes are now commercially available. Freshly ground boron powder should be exposed to air only slowly or it may autoignite.

### 1.1 Preparation of Nanoparticle-Size Elemental Boron

Nanoparticle and nanotube boron are more reactive forms of boron that potentially can result in higher burning rates of solid or slurry fuel propellants. Nanoboron particles may burn more completely than microboron particles, which sometimes become encrusted with  $\text{B}_2\text{O}_3$  slag before they burn to completion. Incomplete combustion results in performance losses. During the past two decades, a substantial amount of effort has been devoted to nanometal powders. There are now periodicals and conferences devoted exclusively to nanoparticles. Most of this effort was aimed at nanoaluminum as a means to increase performance and burning rates of solid rocket propellants. Similar efforts have been directed at nanoboron.

In order to increase the rate of energy release during the combustion of boron and make it a more attractive fuel for propellants and explosives, it is advantageous to prepare it in a nanoparticulate form. Boron nanoparticles have been obtained previ-

ously from diborane by thermolysis at temperatures between 1073 and 2523 K (700 and 2250 °C), although often the size distribution produced is broad or the particles are extensively aggregated [11]. Boron nanoparticles have also been obtained by reduction of boron trihalides with  $H_2$ . The difficulty with nanoboron is that it readily reacts with moisture or air, more readily so than aluminum. It loses some of its combustion value and becomes coated with an oxide layer as soon as it is exposed to air, which slows down the combustion kinetics. Some nanometals are pyrophoric and will autoignite in air, even at room temperature. Several methods are available for making nanoboron. One of the methods uses a thermal plasma system [12]. In another use of this method, a hydrogen thermal plasma jet was employed to prepare nanosized boron powder with hydrogen reduction of  $BCl_3$  vapor [13]. The maximum yield of nanosized boron powder from the hydrogen thermal plasma jet was about 50% with a  $H_2/BCl_3$  ratio of 4.5 : 1, a total feed of  $4.9\text{ m}^3/\text{h}$ , and a plasma power of 25 kW. The average diameter was about 50 nm, and the purity was 90.29%.

Nanoboron can be prepared by decomposition of diborane in a plasma discharge [14]. The reported diameters of boron nanoparticles synthesized in the gas phase and the liquid phase are in the ranges 10–150 and 1–45 nm, respectively.

Another method uses the dry-milling of reactive powders [15–17]. If a mixture of boron trioxide and magnesium is subjected to high-energy ball milling, the grinding forces will eventually trigger a mechanically induced self-sustaining reaction once the particle size is small enough, yielding nanosize boron powder.

Nanoboron can be obtained by ball-milling coarse boron powder in a ball mill with tungsten carbide rollers under either dry or wet conditions [18].

In order to obtain more reproducible results with different batches of nanoboron, the nanoparticles need to be better characterized. A variety of standard particle characterization techniques were applied to fifteen types of particles [19]. The parameters measured were average particle diameter, specific surface area, amount of active content, and oxide layer thickness. Trends in propulsion performance measured using a parameter of great interest to the hybrid rocket community (fuel mass burning rate) in general matched trends in particle characteristics (i.e., active content, surface area), but there were some noticeable exceptions. Other parameters that need to be examined include particle size distribution, degree of agglomeration, reactivity, and thermal effects.

Nanosized boron and  $MgB_2$  (a superconductor) can be prepared by boron oxide solubilization in hot water, cryogenic freezing of the liquid phase, a freezing–drying process, magnesiothermic reduction of boron oxide, and boron purification [20].

Boron combustion is inherently a heterogeneous process, which makes rapid and efficient combustion difficult. An obvious strategy is to increase the surface area/volume ratio by decreasing the particle size. This approach is limited by the fact that boron forms a ~0.5 nm thick native oxide layer that not only inhibits combustion but also consumes an increasing fraction of the particle mass as the size is decreased.

A simple, scalable, one-step process for generating air-stable boron nanoparticles that are unoxidized and soluble in hydrocarbons used ball milling to produce ~50 nm particles that were protected against room temperature oxidation by oleic acid functionalization and optionally coated with a combustion catalyst [21]. The high-energy milling method with subsequent sedimentation to separate aggregates produced gram quantities of nanoparticles in a narrow distribution of particle sizes centered around 50 nm [22].

Ball milling of boron in a hydrogen atmosphere was found to result in hydrogen uptake of up to 5% by mass (36 mol-%) [23]. The nature of the hydrogen binding to boron was probed by a combination of IR spectroscopy, TGA, and MS measurements of the gases evolved during sample heating. The dominant binding mode was found to be that of hydrogen atoms to boron atoms in the surface layer of the particles, and the high hydrogen loading resulted from the production of very high surface area, indicating that gaseous  $H_2$  is an effective agent for promoting size reduction in milling. Hydrogen incorporated into nanoboron was found to be stable for at least a month under ambient conditions. Hydrogen desorption began at ~333 K (~60 °C) and continued as the temperature was increased, with broad desorption features peaking at ~523 and ~723 K (~250 and ~450 °C) and ending at ~1073 K (~800 °C). Hydrogenated boron nanoparticles suspended in a fuel were found to promote more intense combustion upon contact with nitric acid.

Similar to carbon, boron atoms condensing from a hot plasma may also arrange themselves in the shape of nanotubes [24, 25].

### 1.1.1 Protective Coatings for Elemental Boron Particles

The exploitation of the high theoretical heat of combustion of boron has been limited by a few undesirable properties of boron powders. Among them, a resilient oxide layer on the particle surface affects the ignition and combustion of boron particles. Coating boron nanoparticles with a polymer to prevent autoxidation can provide a solution to the problem. The use of an energetic polymer can bring additional heat close to the surfaces of the nanoparticles and facilitate their ignition. Polymer-capped boron nanoparticles were produced by synthesis of surface-functionalized boron to obtain additional hydroxyl functional groups on the particles [26]. These hydroxyl sites were used to graft a diisocyanate and then produce an energetic polymer matrix based on polyurethane chemistry by addition of glycidyl azide polymer, resulting in boron nanoparticles coated with an energetic polymer. This led to improved boron particle combustion.

Energetic polymer coatings evaluated as protective coatings for boron particles include GAP [27, 28]. GAP-coated amorphous-boron-based fuel-rich propellants exhibited more vigorous combustion, higher burning rates, and less residue slag agglomeration than the uncoated baseline propellant. Two stages of combustion were observed

for a dust cloud of GAP-coated boron particles. The burning time was estimated to be approximately 37.5 ms [29].

A synthesis process has been evaluated for the preparation of boron fuel particles coated with titanium [30]. The titanium coating prevents oxide formation on exposure to air and aids in the combustion. Pure boron particles were produced by reaction of sodium vapor with boron trichloride vapor; the products were then expanded through a supersonic nozzle while titanium tetrachloride was added to produce titanium, coating the boron particles. Titanium-coated boron is resistant to oxidation and hydrolysis and has good burning characteristics [31].

Coating with magnesium is a good choice, since magnesium – with its low melting point and low boiling point – is easily vapor deposited on boron powder in a tumbler under vacuum, and some boron powders prepared by a thermite process already contain magnesium [32]. Magnesium-coated boron formulated into solid propellants has good burning characteristics [33, 34]. The same process can also be applied to make aluminum-coated boron.

Even a coating of ammonium perchlorate, a solid oxidizer, can protect the particles from air and moisture [35]. The method used involves dissolving ammonium perchlorate in liquid ammonia, adding a volatile non-solvent diluent and boron particles to the ammonia, and then vaporizing the ammonia and diluent to form a coated product.

Boron carbide is inert to moisture and makes a good coating on boron particles [36]. Boron particles that are coated with a ceramic layer of boron carbide in an atmosphere of decomposing lower hydrocarbons are resistant to oxidation and agglomeration. See also [37].

## 2 Physical Properties of Elemental Boron

Boron exists in the amorphous form and at least two crystalline allotropic forms. The main crystalline forms are  $\alpha$ -rhombohedral,  $\beta$ -rhombohedral, and  $\beta$ -tetragonal. Under special conditions, boron can also be synthesized as its  $\alpha$ -tetragonal and  $\gamma$ -orthorhombic allotropes. Amorphous boron powder and polycrystalline  $\beta$ -rhombohedral boron are the most common forms [38].

One highly unusual allotropic form of boron is borospherene,  $B_{40}$ , which is a cluster molecule containing 40 boron atoms. It is similar to buckminsterfullerene ( $C_{60}$ ), the “spherical” carbon structure, but with a different symmetry. The physical properties of elemental boron are summarized in Table 1.

**Table 1:** Physical properties of elemental boron.

| Property                              | SI units                 | Other units              |
|---------------------------------------|--------------------------|--------------------------|
| Atomic mass                           | 10.811 g/g-atom          | 92.498 g-atom/kg         |
| Density, $\alpha$ -rhombohedral phase | 2.46 g/cm <sup>3</sup>   | —                        |
| Density, $\beta$ -rhombohedral phase  | 2.35 g/cm <sup>3</sup>   | —                        |
| Melting point                         | 2450 K                   | 2177 °C                  |
| Boiling point                         | 3931 K                   | 3658 °C                  |
| Heat of fusion                        | 50.2 $\pm$ 1.7 kJ/g-atom | 12 $\pm$ 0.4 kcal/g-atom |

## 2.1 Thermodynamic Properties of Elemental Boron

The solid- and liquid-phase heat capacities of boron can be calculated with the following equation:

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p^\circ$  is the heat capacity in J mol<sup>-1</sup> K<sup>-1</sup>,  $\tau$  is the absolute temperature in kelvin divided by 1000, and A, B, C, D, and E are constants listed in Table 2.

**Table 2:** Coefficients for thermodynamic properties of solid and liquid boron.

| Temperature range (K) | Solid boron |           | Liquid boron               |
|-----------------------|-------------|-----------|----------------------------|
|                       | 298–1800    | 1800–2350 | 2350–4138                  |
| A                     | 10.18574    | 25.12664  | 31.75003                   |
| B                     | 29.24415    | 1.975493  | 2.556177 $\times 10^{-7}$  |
| C                     | -18.02137   | 0.338395  | -6.456792 $\times 10^{-8}$ |
| D                     | 4.212326    | -0.040032 | 5.616644 $\times 10^{-9}$  |
| E                     | -0.550999   | -2.635578 | 2.705970 $\times 10^{-7}$  |
| F                     | -6.036299   | -14.43597 | 27.94205                   |
| H                     | 0.000000    | 0.000000  | 48.92686                   |

Comment: Values for solid boron are for the  $\beta$ -rhombohedral phase  
Data source: [39]

By definition, the enthalpy of formation of solid boron at 298 K is zero. The solid-phase differential heat of formation of boron as a function of temperature can be calculated with the following equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where  $H^\circ - H^\circ_{298,15}$  is the differential heat of formation in kJ/g-atom,  $\tau$  is the absolute temperature in kelvin divided by 1000, and A, B, C, D, E, F, and H are constants listed in Table 2. The heat of formation of amorphous boron is a little higher than the heat of formation of crystalline boron, which, by definition, would be zero. The heat of formation of amorphous boron is +0.9 kcal/g-atom. The heat of fusion at the melting point is  $50.2 \pm 1.7$  kJ/g-atom ( $12 \pm 0.4$  kcal/g-atom) and the heat of evaporation at the boiling point is 479.56 kJ/g-atom (114.6 kcal/g-atom).

## 3 Chemical Properties of Elemental Boron

### 3.1 Reactions of Elemental Boron

#### 3.1.1 Autoxidation Reactions of Elemental Boron

Amorphous boron will absorb moisture and react with moisture in the atmosphere if it is not stored under dry conditions. The rate of water absorption of amorphous boron is dependent on the particle size and the relative humidity of the atmosphere where boron is stored. Samples that had been stored at various controlled humidities in humidity test chambers showed increased water-soluble boron content. Oxidation of boron to boric acid is accompanied by water absorption; at lower humidities, only about 25% of the sample weight gain was due to oxidation, while oxidation accounted for over half the weight gain above 50% relative humidity (Table 3). Less than 0.03% of the boron stored in dry air in the absence of moisture at 298 K for 13 d was oxidized.

**Table 3:** Cumulative % increase in weight of amorphous boron at various relative humidities.

| Day | Relative humidity, % |      |      |      |      |      |
|-----|----------------------|------|------|------|------|------|
|     | 20                   | 35   | 45   | 66   | 81   | 90   |
| 1   | 0.65                 | 0.83 | 1.02 | 1.30 | 1.76 | 2.1  |
| 10  | 1.05                 | 1.37 | 1.70 | 2.10 | 2.66 | 3.80 |
| 25  | 1.38                 | 2.05 | 2.58 | 3.10 | 3.85 | 5.77 |

Data source: [40]

The reaction between boron and water has been considered as a source of hydrogen gas for fuel cells and automobile propulsion, although at the current cost of boron powder this approach may not be economical [41]. The boron–water reaction can produce 277 g H<sub>2</sub> per kg B. Room-temperature boron hydrolysis is of interest from both scientific and practical perspectives. It was demonstrated that high-purity amorphous boron nanoparticles can be oxidized by water to produce H<sub>2</sub> at room temperature.

### 3.1.1.1 Autoignition Reactions of Elemental Boron

Boron is used as the fuel in many igniter compositions. Therefore, it is important to know the ignition behavior of boron powder in air in the absence and in the presence of solid oxidizers. The autoignition temperature in air is dependent on particle size. Boron is less susceptible to autoignition than aluminum. Replacing aluminum powder in pyrotechnic flash formulations with boron powder raised the autoignition temperature in air per ASTM standard E1492-06 from 623 to 773 K (350 to 500 °C).

## 3.2 Analysis and Specifications of Elemental Boron

Boron purity for pyrotechnic applications is controlled by MIL-SPEC MIL-B51092 [42].

## 3.3 Combustion of Elemental Boron

The use of boron is very attractive for rocket and ramjet applications due to its high heat of combustion on both a gravimetric (58 kJ/g) and a volumetric (136 kJ/cm<sup>3</sup>) basis. The heat of combustion of elemental boron is 58448 kJ/kg = 25150 BTU/lb. Boron slurries in gelled hydrocarbons can be used as fuels in ramjets.

## 4 Applications of Elemental Boron

The main non-pyrotechnic, non-propulsion use of boron, also in the form of boron carbide, is as a neutron absorber in nuclear reactors. Elemental boron is used in many solid igniter formulations such as KNO<sub>3</sub>/B or KClO<sub>4</sub>/B.

### 4.1 Slurries of Boron in Inert Fuels

The best way to protect boron powder particles from air oxidation and moisture hydrolysis is to suspend them in an inert fluid that serves both as a continuous phase suspension and as a fuel. In order to prevent particles from settling, the fluid is usually gelled, similar to metallized gelled fuels with other metal particles. Most of the work has been done with (micron-size or nanosize) boron particles suspended in kerosene. Other inert fuels suitable for boron suspensions are ethanol [43] and ionic liquids. Suspending boron nanoparticles by milling in the presence of a hypergolic energetic ionic liquid (EIL) retains hypergolicity, leading to the ignition of the boron with WFNA [44, 45]. It was found that the ionic liquids 1-methyl-4-amino-1,2,4-triazolium dicyanamide and 1-butyl-3-methylimidazolium dicyanamide bind to boron well enough to resist removal by ultrasonic washing and to protect the boron surface from oxidation during

air exposure of the washed powder. The data suggest that both the cation and the anion of each ionic liquid interact with the boron surface [46]. The interaction of B-H-functionalized boron nanoparticles with alkenes was investigated by a combination of XPS, FTIR, TGA, and helium ion microscopy. Surface B—H bonds were shown to react with terminal alkenes to produce alkyl-functionalized boron particles [47].

## 4.2 Slurries of Boron in Monopropellants

Although most organic nitropropellants such as nitroalkanes or alkyl nitrates are underoxidized, and addition of another fuel such as boron shifts the oxygen balance toward an even more fuel-rich stoichiometry, addition of nanoboron powder to organic monopropellants has been shown to improve performance and combustion rates [48]. The reaction of boron with hydrazine is highly exothermic and forms the basis for a good monopropellant.

# Cyano Compounds and Nitriles

## Cyano Compounds and Nitriles

This chapter contains information on inorganic and organic cyanides. Cyano compounds carry triple bonds. Triple bonds, regardless of whether they are between two carbon atoms or a carbon atom and a nitrogen atom, carry extra energy that make these compounds useful as rocket propellant ingredients. In addition, many of these compounds contain a large amount of nitrogen, which makes them valuable as ingredients in nitrogen gas generators, such as in airbag inflators.

### 1 Inorganic Cyanogen Derivatives

Cyanogen compounds contain a nitrile bond, a carbon–nitrogen triple bond  $C\equiv N$ , which is chemically quite stable. Examples of inorganic cyanogen compounds include hydrogen cyanide  $HC\equiv N$ , cyanogen (dicyanogen)  $N\equiv C-C\equiv N$ , and cyanogen azide  $N\equiv C-N=N\equiv N$ . These compounds have been investigated as high-energy fuels because, when burned with the right oxidizer, they achieve extremely high flame temperatures. Of course, every rocket propulsion student knows that a high flame temperature alone does not imply a good rocket propellant; in addition to a high temperature, one also needs low-molecular-weight combustion products. In this case, the average molecular weight of cyanogen combustion products is relatively high because they contain mostly carbon monoxide and/or carbon dioxide and no or very little hydrogen or water. The products from the combustion of cyanogen with oxygen consist mostly of carbon monoxide and nitrogen, with an average molecular weight of 28 g/mol.

A high flame temperature may be good for a welding torch but it is not easy to tame in a rocket engine. It makes the cooling of rocket engines extremely difficult. Therefore, instead of using cyanogen compounds by themselves, it may be possible to use them as energetic additives to other fuels that contain at least some hydrogen [1].

While the high heats of combustion of cyanogen compounds may not necessarily make them suitable as rocket propellants, they would make good fuels for air-breathing turbojet and ramjet or ram-rocket engines, which have already been demonstrated using methylacetylene as the fuel [2].

All cyanogen compounds are very toxic and would have to be handled with special safety precautions if one ever wanted to use them as rocket propellants. The only cyanogen compound that has ever been used as a rocket propellant is acetonitrile,  $H_3C-C\equiv N$  (see Section 2.1).

## 1.1 Hydrogen Cyanide

Hydrogen cyanide, also known as hydrocyanic acid, prussic acid, formonitrile, HCN, CAS RN [74-90-8],  $M = 27.03 \text{ g/mol}$ , is a colorless, highly toxic liquid with the characteristic odor of bitter almonds. Hydrogen cyanide in aqueous solution was first prepared by Scheele in 1782. The acid occurs naturally among the hydrolysis products of amygdalin and has been the cause of numerous poisoning accidents. Pure hydrogen cyanide is not stable in the liquid state but tends to polymerize to a brown residue. Hydrogen cyanide would not be a good rocket propellant and is discussed here only because it is the parent compound for many other more useful propellant ingredients. Hydrogen cyanide has been detected in the spectra of comet plumes, and there is speculation that it may be a precursor to amino acids in interstellar chemistry. Hydrogen cyanide forms as an unwanted combustion product during fuel-rich combustion of amines and alkylhydrazines in rocket engines. In vacuum rocket engine test facilities where the vacuum is created by steam ejectors, hydrogen cyanide will dissolve in the condensate water. If the condensate water is reused and recycled for the steam generator in a closed loop, hydrogen cyanide may accumulate in the condensate. This has been the case in one of the vacuum test facilities for the third stage of ELDO in Germany in 1965.

Because hydrogen cyanide is very toxic, it is important to detect it quickly in the air in workplaces and take corrective action (i.e., stop the combustion process that emits HCN and increase ventilation). Hydrogen cyanide in air can be detected easily with a reagent-impregnated test paper [3] or with Draeger tubes. Additional information on inorganic cyano compounds is provided in [4].

## 1.2 Cyanogen

Cyanogen, also known as dicyanogen, oxalic acid dinitrile, oxalonitrile, carbon nitride, ethanedinitrile,  $(\text{CN})_2$ , CAS RN [460-19-5], is the simplest representative of the family of cyanogen compounds. It can be used for high-temperature flame studies and as an intermediate in the synthesis of heterocyclic compounds [5]. The hydrolysis of cyanogen leads to oxamide. Cyanogen has been detected in interstellar gas and in the spectra of comet plumes.

### 1.2.1 Preparation of Cyanogen

Cyanogen can be produced in industrial quantities by oxidation of hydrogen cyanide with air in the presence of copper salts as catalysts [6]:

In smaller quantities in the laboratory, cyanogen can be prepared by dehydration of ammonium oxalate or oxamide with phosphorus pentoxide:

by treatment of sodium cyanide or potassium cyanide with copper(II) sulfate, by reacting hydrogen cyanide with chlorine gas, by electrolysis of cyanide solutions or molten cyanides, by heating mercuric cyanide, silver cyanide, or auric cyanide, by pyrolysis of triazine compounds, and by dehydration of glyoxime with acetic anhydride. Cyanogen can be prepared by pyrolysis of diacetylglyoxime, which can be easily prepared from glyoxime [7]. Cyanogen can be prepared from the elements by a consumable carbon electrode in a nitrogen/argon electric arc [8] or by reduction of cyanogen chloride with hydrogen in a quartz tube at 1123 K (850 °C) [9].

### 1.2.2 Physical Properties of Cyanogen

Cyanogen is a colorless, very poisonous gas that can be condensed to a liquid at 252 K = −21.15 °C. Once ignited, the gas will burn in air with a pink-shrouded, very hot flame. Properties of cyanogen are summarized in Table 1.

**Table 1:** Physical properties of cyanogen.

| Property                                               | SI units                      | Other units                     | References |

### 1.2.2.1 Vapor Pressure of Cyanogen

Cyanogen has a very narrow liquid range, only 6° wide. The vapor pressure of liquid cyanogen in the range 252–391.3 K can be calculated from the Antoine equation:

$$\log_{10}P = A - (B/(T + C))$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. The parameters  $A$  through  $C$  are listed in Table 2.

**Table 2:** Parameters of the Antoine vapor pressure equation for cyanogen.

| Temperature range, K | A       | B        | C       |
|----------------------|---------|----------|---------|
| 252–391.3            | 4.51661 | 1041.518 | –21.288 |

Data source: [10]

The vapor pressure of solid cyanogen in the range 202–245 K (–69 to –28 °C) can be calculated from the equation

$$\log_{10}P = -1795.9/T - 0.001464T + 9.42442$$

where  $P$  is the pressure in cm Hg and  $T$  is the temperature in kelvin [12]. The vapor pressure of liquid cyanogen in the range 245–253 K (–28 to –20 °C) can be calculated from the equation

$$\log_{10}P = -1525.7/T - 0.0040842T + 8.96542$$

where  $P$  is the pressure in cm Hg and  $T$  is the temperature in kelvin. See also [15].

### 1.2.2.2 Heat Capacity of Cyanogen

The heat capacity of gaseous cyanogen can be calculated from the Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p$  is the heat capacity in J mol<sup>–1</sup> K<sup>–1</sup>,  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$  are constants, and  $\tau$  is the absolute temperature in kelvin divided by 1000. The coefficients are listed in Table 3. The same coefficients (and others) are used for formulas expressing the standard enthalpy of formation and the standard entropy of the vapor (see Section 1.2.2.3). These equations were obtained by curve fitting data covering the ranges 298–1300 and 1300–6000 K. The heat capacity of liquid cyanogen at 255 K ( $C_p$ ) is 105.73 J mol<sup>–1</sup> K<sup>–1</sup> [12]. See also [16].

**Table 3:** Constants for vapor-phase thermodynamic properties of cyanogen.

| Temperature range, K | 298–1300  | 1300–6000 |
|----------------------|-----------|-----------|
| A                    | 51.69290  | 83.01014  |
| B                    | 36.79351  | 2.209166  |
| C                    | -12.46154 | -0.419735 |
| D                    | 0.701803  | 0.027676  |
| E                    | -0.428743 | -9.308648 |
| F                    | 290.6951  | 264.0342  |
| H                    | 309.0725  | 309.0725  |

Data source: [10]

**1.2.2.3 Heat of Formation and Heat of Combustion of Cyanogen**

The vapor-phase excess enthalpy above the standard enthalpy of formation  $\Delta H^\circ_{f,298}$  of cyanogen can be calculated from the Shomate equation:

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - \Delta H^\circ_{f,298}$$

where A, B, C, D, E, and F are constants and  $\tau$  is the absolute temperature in K divided by 1000. The coefficients are the same as those listed in Table 3. The same coefficients (and others) were used for a formula expressing the heat capacity of the vapor. These equations were obtained by curve fitting data covering the range from 298 to 6000 K.

The heat of combustion of cyanogen gas at 298 K is  $1096.0 \pm 1.8$  kJ/mol ( $261.94 \pm 0.43$  kcal/mol) [14].

**1.2.2.4 Infrared Spectrum of Cyanogen**

The IR spectrum of cyanogen is shown in Figure 1.

**Figure 1:** IR spectrum of cyanogen. Reproduced and modified with permission from [17]

The vibrational Raman spectrum of cyanogen has been obtained in the gas, liquid, and solid states [18]. The three Raman-active fundamentals,  $\nu_1$ ,  $\nu_2$ , and  $\nu_4$ , have been identified in all three phases. Whereas the spectra for the gaseous and liquid phases were consistent with  $D_{\infty h}$  molecular symmetry, the solid-state spectrum clearly showed the presence of the infrared-active and Raman-forbidden  $\nu_3$  mode. This is in contradiction to the XRD results. See also [19].

#### 1.2.2.5 Molecular Structure of Cyanogen

The carbon and nitrogen atoms in cyanogen are in a linear configuration, and the  $\angle \text{C}-\text{C}-\text{N}$  bond angle is  $180^\circ$ . The C—C distance is 1.37 Å and the C—N distance is 1.16 Å.

#### 1.2.3 Chemical Properties of Cyanogen

Cyanogen can serve as an intermediate in syntheses of numerous organic compounds, mostly heterocyclic compounds. A survey of the chemistry of cyanogen lists many reactions involving cyanogen [13].

Although cyanogen has an energy content similar to that of acetylene, cyanogen does not explode in either the solid, liquid, or gaseous state. Under the influence of catalysts, cyanogen can polymerize to a brown solid, such as hydrogen cyanide polymerization products.

A comprehensive study of the stability of pure cyanogen to heat, pressure, chemical additives, and severe mechanical shock found that pure cyanogen was unchanged after 18–23 d at 338 K ( $65^\circ\text{C}$ ), and that it contained only small quantities of solid polymerization products after storage for 100 d under similar conditions [20]. The presence of acids, bases, and salts as contaminants caused an acceleration of the decomposition and polymerization reactions. It was concluded that pure cyanogen did not decompose or polymerize rapidly at moderate temperatures and could be stored safely in Monel or stainless-steel cylinders, even in the absence of a stabilizer. The shock tests of liquid and solid cyanogen indicated that the material is insensitive to mechanical shocks greater than those expected in shipment and laboratory handling.

Cyanogen (dicyanogen) dissociates into cyanogen (CN) free radicals, which can be detected in interstellar space [21, 22].

Paracyanogen, the solid polymeric form of cyanogen, is often a troublesome by-product that forms during reactions of cyanogen, particularly at elevated temperatures. The structure of paracyanogen has not been elucidated but, owing to the chemical inertness and insolubility of paracyanogen, it is presumed to be either a three-dimensional network system or a fused ring system. Paracyanogen is formed when cyanogen is heated to 573–673 K ( $300\text{--}400^\circ\text{C}$ ) at atmospheric pressure. When heated in the presence of an inert carrier purge gas, such as carbon dioxide or nitrogen, paracyanogen depolymerizes to monomeric cyanogen.

### 1.2.4 Safety Properties of Cyanogen

#### 1.2.4.1 Flammable Range of Cyanogen

The flammable range of cyanogen vapor in air is LFL = 6.6 vol.-% to UFL = 32 vol.-%.

### 1.2.5 Toxicity of Cyanogen

Cyanogen (ethanedinitrile) has found a new application as a soil fumigant in agriculture, where it replaces methyl bromide. The use of methylbromide should be discontinued because it is an ozone-depleting chemical with global warming potential. Cyanogen (ethanedinitrile) can be used, often in combination with carbon dioxide, to sterilize soil and control insects, diseases, nematodes, weeds, and other parasites before planting fruit and vegetables, leaving little residue. Unlike most fumigants,  $C_2N_2$  is readily soluble in water, with one volume of water dissolving four volumes of  $C_2N_2$ . In aqueous solutions,  $C_2N_2$  is slowly hydrolyzed to form oxalic acid and ammonia, forming ammonium oxalate. Ammonia adds fertilizer nitrogen to the soil. At low pH,  $C_2N_2$  reacts to form derivatives of formic acid and hydrogen cyanide. The threshold limit value (TLV) for  $C_2N_2$  workplace exposure is 10 ppm.

## 2 Organic Nitriles

Because of their high enthalpies of formation, many cyano compounds have been considered as propellant ingredients [23, 24] and as binders for solid propellants [25].

### 2.1 Acetonitrile

Acetonitrile, also known as methyl cyanide, cyanomethane,  $CH_3C\equiv N$ ,  $C_2H_3N_1$ , CAS RN [75-05-8], was used as an additive to increase the heat of combustion of the HYDYNE fuel mixture, which was used to power the JUPITER-C rocket that launched the first US artificial satellite in 1958. Acetonitrile is often used as a non-aqueous, polar solvent. Acetonitrile,  $H_3CC\equiv N$ , has a structural isomer, methyl isocyanide,  $H_3C-NC$ .

#### 2.1.1 Preparation of Acetonitrile

Acetonitrile can be prepared by addition of hydrogen cyanide to acetylene:

or by dehydration of acetamide:

In industry, most of the acetonitrile is obtained as a by-product of ammoxidation of higher ( $C_{n\geq 2}$ ) hydrocarbons.

### 2.1.2 Physical Properties of Acetonitrile

Physical properties of acetonitrile are listed in Table 4.

The vapor pressure of acetonitrile can be calculated from an Antoine equation,

$$\log_{10}P = A - [B/(T + C)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. Two different sets of constants are offered for this property for two different temperature ranges. The coefficients are listed in Table 5.

**Table 4:** Physical properties of acetonitrile.

| Property                                | SI units                                  | Other units                                  | References |

**Table 5:** Coefficients for the Antoine vapor pressure equation of acetonitrile.

| Temperature range, K | A       | B        | C       | References |
|----------------------|---------|----------|---------|------------|
| 288.3–362.3          | 4.27873 | 1355.374 | –37.853 | [31]       |
| 280.41–300.53        | 5.93296 | 2345.829 | 43.815  | [26]       |

Coefficients were calculated by NIST from the author's data.

The heat capacity of liquid acetonitrile in the range 253–353 K can be calculated from

$$C_p = 1.2838 + 0.0004369T + 5.3125 \times 10^{-6}T^2$$

where  $C_p$  is the heat capacity in  $\text{J g}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. The IR spectrum of liquid acetonitrile is shown in Figure 2.

**Figure 2:** IR spectrum of liquid acetonitrile liquid. Reproduced and modified with permission from [32].

### 2.1.3 Chemical Properties of Acetonitrile

All cyanides are poisonous. Thus, the OSHA PEL TWA of methyl cyanide is 40 ppm and the IDLH is 500 ppm. The LC50 in rabbits is 2828 ppm.

Using standard textbook methods for synthesizing more energetic materials, attempts were made to synthesize the energetic acetonitrile derivatives nitroacetonitrile  $\text{O}_2\text{N}-\text{CH}_2-\text{CN}$  (mononitroacetonitrile, nitrocyanomethane) and azidoacetonitrile  $\text{N}_3-\text{CH}_2-\text{CN}$ , but both compounds are detonable and quite sensitive to shock. Nitroacetonitrile and dinitroacetonitrile form salts with alkali metal hydroxides and ammonium hydroxide.

### 2.1.4 Rocket Fuel Blends Containing Acetonitrile

Acetonitrile mixed with UDMH was an essential fuel component in the REDSTONE rocket that launched the first US satellite. One fuel mixture used at that time consisted of 50% UDMH, 39% diethylene triamine, and 10% acetonitrile. A mixed amine fuel, MAF-1, was composed of 50.5% UDMH, 40.5% diethylene triamine (DETA), and 9.0% acetonitrile. MAF-5 consisted of 29.5% UDMH, 50.5% diethylene triamine (DETA), and 20.0% acetonitrile.

When an equimolar quantity of acetonitrile was mixed with anhydrous hydrazine, a drop in temperature of about  $10^\circ\text{C}$  occurred, indicating endothermic mixing [33]. However, this solution showed liquid phase separation at  $266.6 \text{ K}$  ( $-6.5^\circ\text{C}$ ). Methyl alcohol was added to increase the mutual miscibility of the two liquids. An equimolar mixture of the three components froze at  $214.6 \text{ K}$  ( $-58.5^\circ\text{C}$ ).

## 2.2 Propionitrile

Propionitrile, also known as ethyl cyanide, cyanoethane, propanenitrile,  $\text{C}_2\text{H}_5\text{CN}$ , CAS RN [107-12-0], has physical properties similar to acetonitrile and could be used for the same purposes. Properties of propionitrile are summarized in Table 6.

**Table 6:** Physical properties of propionitrile

| Property                                | SI units                                  | Other units                                       | References |
|-----------------------------------------|-------------------------------------------|---------------------------------------------------|------------|
| Molecular mass                          | 55.0785 g/mol                             | 18.156 mol/kg                                     | [10]       |
| Freezing point                          | $180 \pm 7 \text{ K}$                     | $-93 \pm 7 ^\circ\text{C}$                        |            |
| Boiling point                           | 370 K                                     | $97 ^\circ\text{C}$                               |            |
| Triple point                            | 180.37 K                                  | $-92.78 ^\circ\text{C}$                           |            |
| Critical temperature                    | 561.3 K                                   | $288.2 ^\circ\text{C}$                            |            |
| Critical pressure                       | 42.60 bar                                 | 42.04 atm                                         |            |

## 2.3 Cyanoacetylene

Cyanoacetylene, also known as ethynylcyanide,  $\text{HC}\equiv\text{C}-\text{C}\equiv\text{N}$ ,  $\text{C}_3\text{H}_1\text{N}_1$ , CAS RN [68010-34-4],  $M = 51.0467 \text{ g/mol}$ , is a very energetic compound that burns in air or oxygen with a very hot flame. Cyanoacetylene has been detected in interstellar gas. It may even be present in the hydrocarbon-rich atmosphere of Titan.

Cyanoacetylene boils at 314–316 K (41–43 °C) and can be made by dehydration of propargyl aldehyde oxime with acetic anhydride [34–36]:

After examining the IR and Raman spectra of cyanoacetylene, band assignments were made for eight of the nine fundamental frequencies that explained the observed combination tones very satisfactorily [37]. All features of the spectra are compatible with  $D_{\infty h}$  symmetry, in particular the IR band contours, the lack of coincidences between IR and Raman frequencies, and the operation of selection rules for the combination tones.

The IR spectra of gaseous, liquid, and solid cyanoacetylene have been observed [38] in the region from 450 to 3400  $\text{cm}^{-1}$ . Five of the seven fundamental vibrational frequencies expected for cyanoacetylene based on a linear structure have been assigned, and the remaining frequency has been estimated from the observed combination bands. Based on these data, a force constant calculation was carried out using a simple valence potential function.

IR band assignments for a total of 28 frequencies – the complete set – were made with improved confidence by comparing the spectrum of the normal hydrogen-containing cyanoacetylene with that of its deuterated isotopomer [39].

Crystalline cyanoacetylene is monoclinic, with unit cell parameters of  $a = 6.96 \text{ \AA}$ ,  $b = 6.90 \text{ \AA}$ ,  $c = 3.84 \text{ \AA}$ ,  $\beta = 110.5^\circ$  [40]. The probable space group is  $P2_1/m$ , with two molecules per unit cell. Cyanoacetylene molecules are joined together by  $\text{CH}\cdots\text{N}$  hydrogen bonds into parallel, approximately linear, infinite chains that are nearly close packed. The bond lengths are:  $\text{C}\equiv\text{N}$  1.14  $\text{\AA}$ ,  $\text{C}-\text{C}$  1.38  $\text{\AA}$ ,  $\text{C}\equiv\text{C}$  1.18  $\text{\AA}$ , and  $\text{C}-\text{H}$  0.9  $\text{\AA}$ . The molecules are linear within experimental error. The enthalpy of formation of cyanoacetylene is +529 kJ/mol (+126.5 kcal/mol) [41]. For comparison, the enthalpy of formation of dicyanodiacetylene is +751 kJ/mol (+179.4 kcal/mol) (estimated).

## 2.4 Dicyanoacetylene

Cyanogen compounds with more than two  $\text{C}\equiv\text{N}$  or  $\text{C}\equiv\text{C}$  triple bonds have even higher energy contents than cyanogen  $\text{N}\equiv\text{C}-\text{C}\equiv\text{N}$  itself. Higher energy is achieved by inserting one or two acetylene  $\text{C}\equiv\text{C}$  linkages between the terminal  $-\text{C}\equiv\text{N}$  groups. The first compound of this kind to be synthesized was dicyanoacetylene, also known as acetylene dicarbonic acid dinitrile, 2-butyne dinitrile, 1,2-dicyanoacetylene, dicyanoethyne, carbon subnitride,  $\text{N}\equiv\text{C}-\text{C}\equiv\text{C}-\text{C}\equiv\text{N}$ , CAS RN [1071-98-3],  $M = 76.0562 \text{ g/mol}$ . This compound is a solid at cool room temperature but melts at 293.5–294 K (20.5–21  $^\circ\text{C}$ ) to give a clear, colorless liquid and boils at 349 K at 100.4 kPa (76  $^\circ\text{C}$  at 753 mmHg) [42]. It readily sublimates at room temperature but gradually decomposes and turns brown during storage at room temperature. The molten compound has a density of 0.9703  $\text{g/cm}^3$  at 298 K (25  $^\circ\text{C}$ ). The heat of combustion is 2160 kJ/mol = 516 kcal/mol = 6790 cal/g. Early data for this compound included a standard enthalpy of formation  $\Delta H_f^{298}$  of the liquid of +493.7 kJ/mol = +118.0 kcal/mol [27] and an enthalpy of formation  $\Delta H_f^{298}$  of the vapor of +627 kJ/mol (149.81 kcal/mol). NIST-Chase [43] gives an enthalpy of formation of the vapor of +533.46 kJ/mol (+127.5 kcal/mol), and NIST-Armstrong [44] gives the enthalpy of formation of the liquid as +500.4 kJ/mol (+119.6 kcal/mol). This compound can instantly explode, forming just carbon soot and nitrogen. During its combustion with oxygen in a calorimeter bomb, some of it decomposed instead of burned, and the heat of combustion had to be corrected for the amount of unburnt carbon found. The corrected heat of combustion of the liquid is 2074 kJ/mol (495.7 kcal/mol), and the

heat of formation derived from this number is +495.5 kcal/mol (+118.4 kcal/mol) [44, 45]. See also [46–48].

It is interesting to note that methyl cyanide  $\text{H}_3\text{CCN}$ , cyanoacetylene  $\text{HC}_3\text{N}$ , dicyanoacetylene  $\text{C}_4\text{N}_2$ , cyanodiacetylene  $\text{HC}_5\text{N}$ , cyanotriacetylene  $\text{HC}_7\text{N}$ , and cyanotetraacetylene  $\text{HC}_9\text{N}$  have been detected in interstellar space by radioastronomy [49]. They may be precursors to amino acids and constituents of tholins.

Dicyanoacetylene can be prepared by the pyrolysis of 1,2-dichloro-1,2-dicyanoethylene [50]. One synthetic method for dicyanoacetylene starts with acetylene and proceeds via propiolic acid, propiolic acid amide, and dehydration [51]. Forming the amide in liquid ammonia at low temperature and suspending  $\text{P}_2\text{O}_5$  powder in xylene for dehydration improves the overall yield.

The infrared and Raman spectra of dicyanoacetylene were analyzed [52]. Assignments were given for eight of the nine fundamental frequencies that explained the observed combination tones very satisfactorily. All features of the spectra were compatible with  $D_{\infty h}$  symmetry, in particular the IR band contours, the lack of coincidences between IR and Raman frequencies, and the operation of selection rules for the combination tones.

In a continuation of that work, the IR spectrum of dicyanoacetylene was extended down to  $320\text{ cm}^{-1}$  and one more combination tone was located [53]. When a larger sample and a better instrument was used, 15 Raman lines were detected instead of the four reported earlier, allowing the vibrational assignments to be revised and extended. All but one of the fundamentals have been observed directly, and the one exception ( $107\text{ cm}^{-1}$ ) is well established from combination tones. The totally symmetric fundamentals have been reassigned to 2290, 2119, and  $692\text{ cm}^{-1}$ .

Near to 278 K ( $5^\circ\text{C}$ ), dicyanoacetylene forms monoclinic crystals belonging to the space group  $C_{2h}-P2_1a$  [54]. The unit cell dimensions are  $a = 8.93\text{ \AA}$ ,  $b = 6.04\text{ \AA}$ ,  $c = 3.86\text{ \AA}$ ,  $\beta = 99^\circ 20'$ . The two molecules per unit cell are linear and have a center of symmetry. Bond lengths within the molecule are:  $\text{C}\equiv\text{N}1.14\text{ \AA}$ ,  $\text{C}-\text{C}1.37\text{ \AA}$ , and  $\text{C}\equiv\text{C}1.19\text{ \AA}$ .

## 2.5 Dicyanodiacetylene

An even more energetic compound is obtained by inserting not just one, but two acetylene groups between the terminal cyanogen groups:  $\text{N}\equiv\text{C}-\text{C}\equiv\text{C}-\text{C}\equiv\text{C}-\text{C}\equiv\text{N}$ . The compound thus obtained is called dicyanodiacetylene, butadiyne dicarbonic acid dinitrile, hexadiynedinitrile, hexacarbon dinitride, CAS RN [16419-78-6],  $M = 100.0776\text{ g/mol}$ .

Dicyanodiacetylene was first synthesized by the action of aqueous potassium ferricyanide on the cuprous derivative of propiolonitrile (cyanoacetylene). With newer methods, yields as high as 36% have been obtained [55]. The product was characterized as dicyanodiacetylene ( $C_6N_2$ ) by elementary analysis and molecular weight determinations and by conversion on hydrogenation to hexamethylenediamine. Dicyanodiacetylene is an unstable, volatile, white solid with a marked irritating odor. It can be obtained by sublimation in a stream of carbon dioxide gas as fine, elongated crystals that melt at 337.6–338.6 K (64.5–65.5 °C). Dicyanodiacetylene gradually turns brown at room temperature but may be stored at 273 K (0 °C) without decomposition. This discoloration is more rapid in the presence of water.

This compound has a very high heat of combustion and gives very high flame temperatures when burned in oxygen or in air [46, 56]. At 335 K = 62 °C it has a vapor pressure of 10.66 kPa = 80 mm Hg. The extrapolated boiling point would be 427 K = 154 °C, but it is unstable at that temperature and needs to be sublimed under vacuum for purification. The heat of vaporization is 30.25 kJ/mol = 7.23 kcal/mol. The heat of sublimation is 35.9 kJ/mol at 295–335 K.

Dicyanodiacetylene,  $N\equiv C-C\equiv C-C\equiv C-C\equiv N$ , was prepared by the sequence of reactions

and the IR spectrum of dicyanodiacetylene was measured from 35 to 4000  $cm^{-1}$  in the vapor and solution phases [57]. Raman spectra with polarizations were obtained for solutions.  $D_{\infty h}$  symmetry is fully satisfactory for assigning IR absorption and Raman fluorescence lines, and most fundamentals have been assigned. All other candidate symmetries present serious problems. The three polarized Raman lines at 2235, 2183, and 1287.5  $cm^{-1}$  are surely  $\nu_1$ ,  $\nu_2$ , and  $\nu_3$ , respectively, but there was no polarized line for  $\nu_4$ . The experimental evidence clearly supported the expected linear symmetrical structure. As of 1967, dicyanodiacetylene was believed to be the longest confirmed linear molecule known.

## 2.6 Malonic Acid Dinitrile

Malonic acid dinitrile, also known as dicyanomethane, methylene cyanide, malononitrile,  $H_2C(CN)_2$ ,  $C_3H_2N_2$ , CAS RN [109-77-3],  $M = 66.0614$  g/mol, is a useful intermediate in the synthesis of other energetic chemicals. It is not anticipated that it would be used as a rocket fuel as such.

Malonic acid dinitrile can be prepared by reacting acetonitrile and cyanogen chloride in the gaseous phase at temperatures between 1053 and 1473 K (780–1200 °C) [58]. Yields exceeding 80% can be obtained when the reactants flow through the reactor in a condition exceeding laminar flow and extending into turbulent flow, with molar ratios of acetonitrile to cyanogen chloride of 4:1 and with residence times at reaction temperatures of less than 5 s. Preheating the acetonitrile to 873–923 K (600–650 °C) considerably increased the space–time yield (capacity) of the reactor, and use of an excess of acetonitrile aided in the removal of HCl [59].

Malonic acid dinitrile melts at 305 K (32 °C) and boils at 493 K (220 °C) at atmospheric pressure or at 382 K at a reduced pressure of 0.027 bar.

The heat of formation of malonic acid dinitrile vapor is +265.7 kJ/mol (+63.5 kcal/mol) [60]. Other sources give the heat of formation of solid malonic acid dinitrile as  $+187.9 \pm 0.2$  kJ/mol. Dicyanomethane,  $\text{CH}_2(\text{CN})_2$ , has an active proton that acts as an acid ( $\text{p}K_{\text{a}} = 11.2$ ) and can form salts with strong bases. Dicyanomethanide salts of heterocyclic amines such as triazole or tetrazole are high-nitrogen compounds that are useful as additives for gas generants. Some have enthalpies of formation as high as 1579 kJ/mol [61].

Dicyanomethanide salts of heterocyclic amines such as imidazole have very low melting points and qualify as ionic liquids. These ionic liquids are particularly useful as hypergolic ionic liquids with very low vapor pressures, potential replacements for MMH (see the chapter “Ionic Liquids” in *Encyclopedia of Liquid Fuels*). Nitrodicyanomethanide and dinitrocyanomethanide anions can be used in similar applications.

## 2.7 Other Nitrile Compounds

### 2.7.1 Dinitroacetonitrile

Dinitroacetonitrile,  $(\text{O}_2\text{N})_2\text{CHC}\equiv\text{N}$ ,  $\text{C}_2\text{H}_1\text{N}_3\text{O}_4$ , can be prepared by hydrolysis of dinitrocyanoacetic acid esters or by reduction of trinitroacetonitrile with hydrogen sulfide or bromide ion. The hydrogen atom is acidic, and it forms salts with a variety of bases. The product is most stable if crystallized with four molecules of water as a hydrate that melts at 311–313 K (38–40 °C). Dinitroacetonitrile has never been isolated in a pure, anhydrous state. Instead of isolating the pure compound, it is best isolated in the form of its salts with alkali metals or organic amines [62, 63]. The potassium salt of dinitroacetonitrile is sparingly soluble in most solvents and best suited for isolation, and most other salts can be prepared from the sodium salt. Dinitroacetonitrile can be used for the synthesis of dinitrocyanoethanol by reaction with formaldehyde [64], dinitroacetamide [65], and esters of dinitrocyanoacetic acid [66].

### 2.7.2 Trinitroacetoneitrile

Trinitroacetoneitrile, also known as trinitrocyanomethane, cyanotrinitromethane,  $(\text{O}_2\text{N})_3\text{CC}\equiv\text{N}$ ,  $\text{C}_2\text{N}_4\text{O}_6$ ,  $M = 176.0446 \text{ g/mol}$ , CAS RN [630-72-8], forms yellow volatile crystals with a pungent odor that melt at 314.6 K (41.5 °C) and explode on rapid heating to 493 K (220 °C). It is a very hazardous substance and its synthesis would be avoided if alternatives were available. It is soluble in ether but reacts with water or alcohols. In the Trauzl test, the lead block expansion is 182% of that of picric acid. The drop weight sensitivity is 15 cm or less with a 2 kg weight.

Trinitroacetoneitrile can be made by complete nitration of cyanoacetic acid in carbon tetrachloride as the solvent:

When the molar ratio of nitric acid to cyanoacetic acid was reduced to 2:1 or 1:1, and with less sulfuric acid, 3,4-dicyanofuroxan was obtained as the major by-product.

The heat of combustion of trinitroacetoneitrile is  $961 \pm 1 \text{ kJ/mol}$ , and its enthalpy of formation  $\Delta H_f^\circ \text{ solid} = +174 \pm 1 \text{ kJ/mol}$  [67].

### 2.7.3 Tetracyanomethane

Tetracyanomethane, also known as methanetetracarbonitrile,  $\text{C}(\text{C}\equiv\text{N})_4$ ,  $\text{C}_5\text{N}_4$ , CAS RN [24331-09-7],  $M = 116.0803 \text{ g/mol}$ , is a pernitride containing only carbon and nitrogen [48, 68].

The silver salt of tricyanomethane (*cyanofom*) reacts with cyanogen chloride to form tetracyanomethane and AgCl [69].

Tetracyanomethane is crystalline, sublimes at 333 K (60 °C) under vacuum, begins to decompose at 433 K (160 °C), and is soluble in polar solvents. Tetracyanomethane is stable as long as moisture is excluded. If a solution is allowed to sit in moist air, it discolors to yellow and forms an insoluble orange residue (a polymer).

There is a contradiction in the literature about the crystal structure of tetracyanomethane. One source described the crystals as trigonal, space group  $R3c$ . Tetracyanomethane,  $\text{C}(\text{CN})_4$ , is monoclinic and crystallizes in space group  $Cc$  or  $C2/c$  with  $a = 9.361 \text{ \AA}$ ,  $b = 8.881 \text{ \AA}$ ,  $c = 6.241 \text{ \AA}$ ,  $\beta = 91.30^\circ$ , and with four molecules per unit cell [70]. No crystallographic phase transitions were observed at standard pressure between 123 K (−150 °C) and the decomposition temperature of 433 K (+160 °C). An analysis of the data available for several methylcyanomethane compounds indicated that dipole–dipole interactions are more important in these compounds than hydrogen-bond formation.

Other publications described the crystal structure of tetracyanomethane as trigonal with hexagonal axes  $a = 9.062(2) \text{ \AA}$  and  $c = 11.625(3) \text{ \AA}$ ,  $Z = 6$ , space group  $R3c$  [71]. The molecule has full tetrahedral symmetry within experimental error, and its aver-

age bond lengths are: C—C 1.481, corrected to 1.488 Å; C≡N 1.147, corrected to 1.168 Å. The structure is a trigonal distortion of the cubic SiF<sub>4</sub> structure. One nitrogen atom points directly at the central carbon atom of an adjacent molecule, with a N...C (in CN) distance of 3.03 Å. The remaining three (equivalent) nitrogen atoms point approximately at the central carbon atoms of three adjacent molecules, with N...C (in CN) distances of 3.00, 3.10, and 3.19 Å. These short distances are regarded as evidence of donor–receptor interactions. The Britton [71] and Rubin [70] papers contradict each other. This needs clarification.

Tetracyanomethane was burned in a rotating-bomb combustion calorimeter in order to determine its thermodynamic properties. The standard enthalpy of combustion  $\Delta H_c(c)$  was  $2579 \pm 1.7 \text{ kJ/mol} = 616.43 \pm 0.4 \text{ kcal}_{th}/\text{mol}$ , which yields a standard enthalpy of formation  $\Delta H_f^\circ(c)$  of  $+611.6 \pm 1.8 \text{ kJ/mol} = +146.18 \pm 0.43 \text{ kcal/mol}$  [72]. The enthalpy of formation of tetracyanomethane vapor is  $672.8 \pm 9.2 \text{ kJ/mol}$ . The mean bond dissociation energy is  $\langle D \rangle(\text{C}—\text{CN}) = 469 \text{ kJ/mol} = 112 \text{ kcal/mol}$ .

The IR spectrum of tetracyanomethane dissolved in acetonitrile solution was recorded and a full set of fundamental frequencies were assigned to vibrations and oscillations in the molecule [73]. A normal coordinate analysis was then carried out and the values of the calculated force constants were compared with those of related molecules. Some thermodynamic functions were computed from the spectroscopic data.

#### 2.7.4 Tetracyanoethylene

Tetracyanoethylene, also known as tetracyanoethene, ethenetetracarbonitrile,  $(\text{CN})_2\text{C}=\text{C}(\text{CN})_2$ , C<sub>6</sub>N<sub>4</sub>, CAS RN [670-54-2],  $M = 128.0910 \text{ g/mol}$ , is a dienophile and forms  $\pi$  complexes and charge-transfer complexes with many aromatic compounds. It is the strongest  $\pi$  acid in the inventory. Heats of reaction for the formation of complexes between tetracyanoethylene and methylbenzenes were found to range from  $-9.6 \text{ kJ/mol}$  ( $-2.3 \text{ kcal/mol}$ ) for benzene to  $-29.3 \text{ kJ/mol}$  ( $-7.0 \text{ kcal/mol}$ ) for pentamethylbenzene. Tetracyanoethylene is not likely to be used as a rocket propellant, but it has been tested for some pyrotechnic formulations (IR decoy flares).

Tetracyanoethylene has been synthesized from malononitrile by four different methods: by reaction with sulfur monochloride, by chlorination/dehydrochlorination of malononitrile in the vapor phase, by condensation with malononitrile followed by pyrolysis of the product, and by debromination of dibromomalononitrile with copper powder in boiling benzene.

Tetracyanoethylene is a colorless, crystalline solid that sublimes readily at temperatures above 393 K (120 °C) at atmospheric pressure and melts at 471–473 K (198–200 °C) in a sealed capillary. The IR spectrum of tetracyanoethylene has a divided band in the nitrile region that is characteristic of conjugated, unsaturated nitriles. The heats of combustion and sublimation of tetracyanoethylene are 3021 and 78 kJ/mol (722 and 18.65 kcal/mol), respectively. The enthalpy of formation of solid tetracyanoethylene is  $+633 \pm 2 \text{ kJ/mol}$ . Given this high enthalpy of formation, it should make

**Figure 3:** Molecular structure of tetracyanoethylene.

a good rocket propellant ingredient, but it lacks the hydrogen. The molecular structure of tetracyanoethylene is illustrated in Figure 3.

Additions to the double bond of tetracyanoethylene occur rapidly, even at room temperature, with several types of reagents, including dienes, aromatics, ketones, and hydrogen. Tetracyanoethylene is an unusually active dienophile; its reaction with butadiene and other 1,3-dienes gives tetracyanocyclohexenes [74].

The heats of combustion of several cyanocarbons were measured, as well as their heats of vaporization (from vapor pressures), and heats of solution were determined in order to calculate the heats of formation [75]. The cyano-olefins tricyanoethylene and tetracyanoethylene have negative stabilization energies, indicating that electrostatic repulsion between the highly polar cyano groups predominates over electronic delocalization stabilization ( $-62.8$  and  $-113$  kJ/mol =  $-15$  and  $-27$  kcal/mol, respectively).

### 2.7.5 Hexacyanoethane

Hexacyanoethane is a colorless solid that decomposes in a sealed tube above 403 K (130 °C). Its most striking property is its instability, decomposing spontaneously at room temperature to tetracyanoethylene and polymeric materials. It can be sublimed at 348 K and 0.67 kPa (75 °C at 2 mm Hg), but some decomposition to tetracyanoethylene and, presumably, cyanogen occurs during sublimation. It has been stored at 195 K ( $-78$  °C) for long periods without change.

### 2.7.6 Azodicarbonitrile

Azodicarbonitrile,  $\text{N}\equiv\text{C}-\text{N}=\text{N}-\text{C}\equiv\text{N}$ ,  $\text{C}_2\text{N}_4$ , has been synthesized in good yield by the pyrolysis of cyanogen azide at 473 K (200 °C) [76, 77]. The reaction in the vapor phase is believed to involve cyanonitrile ( $[\text{N}=\text{C}=\text{N}]$ ) as an intermediate:

Azodicarbonitrile is a crystalline, orange-red, volatile solid with a melting point of 308.6–310.1 K (35.5–37 °C). Vapor pressure measurements and gas liquid chromatography indicated that both *cis* and *trans* isomers are present; however, these have not been separated [78]. The *trans* isomer is energetically favored by 83 kJ/mol (20 kcal/mol). Vapor phase decomposition of azodicarbonitrile at 373 K (100 °C) is slow. However, crystalline azodicarbonitrile detonates when mechanically shocked or heated in a closed vessel. Because of the hazardous nature of pure cyanogen azide, azodicarbonitrile has been synthesized only on a limited scale. Azodicarbonitrile is soluble without reaction in benzene, acetonitrile, ethyl acetate, 1,1,2-trichloro-1,2,2-trifluoroethane, or nitromethane. It is decomposed by methanol, water, or ether. The reaction of azodicarbonitrile with 1,3-dienes causes the red color to disappear, and can be used as an analytical reagent for conjugated double bonds.

# Cycloaliphatic Hydrocarbons

## Introduction

*Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. The topic of hydrocarbon fuels had to be subdivided into several smaller chapters, which were easier to arrange in alphabetical order into five sub-volumes of equal size. The titles of the eight hydrocarbon chapters are “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.”

## 1 Cycloaliphatic Hydrocarbons

Cycloaliphatic (“hydroaromatic,” “alicyclic”) hydrocarbons may have certain advantages over open-chain hydrocarbons. Alicyclic compounds are both aliphatic and cyclic. They contain one or more all-carbon rings that may be either saturated or unsaturated, but they do not have aromatic character and do not contain a heteroatom. Alicyclic compounds may have one or more aliphatic side chains attached. Cycloalkanes are named by adding the prefix “cyclo” to their normal alkane counterparts of the same carbon count: cyclopropane, cyclobutane, cyclopentane, cyclohexane, etc. The larger cycloalkanes, with more than 20 carbon atoms, are also called cycloparaffins. The simplest alicyclic compounds are the monocyclic cycloalkanes: cyclopropane, cyclobutane, cyclopentane, cyclohexane, cycloheptane, and cyclooctane. Cycloalkanes are also called naphthenes but should not be confused with naphthalene, which is an aromatic hydrocarbon.

Cycloaliphatic hydrocarbons occur naturally as constituents of petroleum and crude oil and in plant oils (terpenes). The percentage of cycloaliphatic hydrocarbons in these fossil fuels varies significantly from source to source. Oil pumped in the Caucasus region was one of the first petroleums to be identified as having a high content of cycloaliphatic hydrocarbons compared to oil pumped in other regions of the world. The most common cycloaliphatic hydrocarbon is cyclohexane, which is easily dehydrogenated to benzene or, in a reversal of this reaction, easily made from benzene by hydrogenation. Six-ringed cycloaliphatic hydrocarbons are thermally more stable than rings containing fewer or more than six carbon atoms in the ring. Other cycloaliphatic hydrocarbons are contained in turpentine distilled from the resins of certain coniferous trees, giving the name “terpenes” to this group of hydrocarbons.

In addition to occurring naturally, certain cycloaliphatic compounds with increased internal energy due to strained ring (three-ring and four-ring) structures are synthesized in the laboratory, and some are produced industrially, but they do not occur in nature in the unsubstituted hydrocarbon form. Many of these hydrocarbons

combine more than one ring in the molecule, and many of these are used as fuels in air-breathing cruise missiles.

The potential of increasing the rocket performance of hydrocarbon fuels by using three- and four-ringed compounds was recognized relatively early in the sequence of historical events leading to today's state of rocket technology [1].

If one or more of the carbon atoms in an alicyclic compound is replaced by B, N, O, S, Si, or another heteroatom, we arrive at the vastly complex group of heterocyclic compounds. Some of these are used as rocket fuels, and others are or have been used as monopropellants, e.g., ethylene oxide. These fuels are discussed in the chapters "Ethers" and "Heterocyclic Amines" of this volume.

There are numerous literature summaries on the chemistry and applications of cycloaliphatic hydrocarbons [2–6]. In a review of fuels for air-breathing supersonic propulsion, cycloaliphatic hydrocarbons were identified to offer the best compromise for future supersonic propulsion [7]. Multi-cyclic, strained, and caged fuels have higher density and higher energy content than open-chain hydrocarbons and must be synthesized from other precursors [8].

## 2 Cyclopropane

Cyclopropane, trimethylene,  $C_3H_6$ , CAS RN [75-19-4], is a strained ring molecule, the lowest member of the cycloaliphatic hydrocarbon family of compounds. It has a high heat of combustion but is difficult to synthesize in quantity and therefore not used as a rocket propellant. However, hydrocarbons containing cyclopropyl rings as attachments have been used as rocket propellants (Syntin, see Section 2.3). This is why we include cyclopropane in this chapter. See also [9, 10].

### 2.1 Preparation of Cyclopropane

Cyclopropane was first prepared by dehalogenating 1,3-dibromopropane with sodium metal. Later the sodium metal was replaced by zinc metal in moist ethanol. The reaction also works with 1-bromo-3-chloropropane or 1,3-dichloropropane.

The conversion of ethene with methylene iodide and a brass alloy in ether gave a yield of 29% cyclopropane [11–14]:

The reaction of olefins with dialkyl zinc and methylene iodide gives cyclopropane derivatives [15]. Another source of methylene carbenes is the photolysis of dia-

zomethane. The light-induced reaction of diazomethane with olefins gives a mixture of cyclopropane derivatives.

## 2.2 Physical Properties of Cyclopropane

The physical properties of cyclopropane are summarized in Table 1.

**Table 1:** Physical properties of cyclopropane.

| Property                            | SI units                                  | Other units                                  | References |
|-------------------------------------|-------------------------------------------|----------------------------------------------|------------|
| Molecular mass                      | 42.0797 g/mol                             | 23.764 mol/kg                                |            |
| Freezing point                      | 145.54 K                                  | −127.61 °C                                   | [16]       |
| Boiling point                       | 240.3 K                                   | −32.85 °C                                    |            |
| Density at normal boiling point     | 0.68 g/cm <sup>3</sup>                    | 0.68 g/cm <sup>3</sup>                       |            |
| Standard enthalpy of formation, gas | +53.3 kJ/mol                              | +12.74 kcal/mol                              | [17, 18]   |
| Heat capacity, liquid at 150 K      | 75.81 J mol <sup>−1</sup> K <sup>−1</sup> | 18.12 cal mol <sup>−1</sup> °C <sup>−1</sup> | [16]       |
| Heat capacity, liquid at 240 K      | 81.34 J mol <sup>−1</sup> K <sup>−1</sup> | 19.44 cal mol <sup>−1</sup> °C <sup>−1</sup> |            |
| Enthalpy of fusion                  | 5443 J/mol                                | 1301 cal/mol                                 |            |
| Enthalpy of vaporization at 240 K   | 20.054 kJ/mol                             | 4.793 ± 3 kcal/mol                           |            |
| Entropy, gas, at 298 K              | 237.8 J mol <sup>−1</sup> K <sup>−1</sup> | 56.84 cal mol <sup>−1</sup> °C <sup>−1</sup> |            |
| Critical temperature                | 398.0 ± 0.3 K                             | 124.9 ± 0.3 °C                               | [17]       |
| Critical pressure                   | 55.4 ± 0.5 bar                            | 54.7 atm                                     |            |
| Critical specific volume            | 0.162 L/mol                               | —                                            |            |
| Critical density                    | 6.15 ± 0.05 mol/L                         | —                                            |            |

The vapor pressure of cyclopropane in the range between 183 and 241 K can be calculated from

$$\log P = 9.03877 - 1348.2/T - 0.00823 T + 7.45 \times 10^{-6} T^2$$

where  $P$  is the vapor pressure in cmHg and  $T$  is the temperature in kelvin [16]. The same data in the form of an Antoine equation is

$$\log P = 4.05015 - [870.393/(T - 25.063)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. The Wagner equation for the vapor pressure of cyclopropane is

$$\ln\left(\frac{P}{P_c}\right) = (A\tau + B\tau^{1.5} + C\tau^3 + D\tau^6) / \left(\frac{T}{T_c}\right)$$

where  $T$  is temperature in K,  $\tau = 1 - (T/T_c)$  with the following constants  $A = -6.60088$ ,  $B = 1.27594$ ,  $C = -1.78063$ , and  $D = -2.07475$  [19]. From the same source, the density

of cyclopropane for  $T/T_c = 0.38$  to 1.0 can be expressed by the following generalized Rackett equation

$$\ln(\rho') = A + B\left(\frac{1-T}{C}\right)^D$$

where  $\rho'$  is the density in mol/L,  $T$  is the temperature in kelvin, and the constants are as follows:  $A = 1.42272$ ,  $B = -1.63206$ ,  $C = 399.266$ , and  $D = 0.187411$ .

### 2.2.1 Optical Properties of Cyclopropane

The infrared (IR) spectrum of cyclopropane has absorption bands at 3125, 3030, 1031 to 1020  $\text{cm}^{-1}$ , and between 909 and 833  $\text{cm}^{-1}$  (3.2, 3.3, 9.7 to 9.8  $\mu\text{m}$ , and between 11 and 12  $\mu\text{m}$ ) (Figure 1).

**Figure 1:** Infrared spectrum of cyclopropane. (Reproduced and modified with permission from [20])

### 2.2.2 Molecular Structure of Cyclopropane

The tetrahedron bond angle of the stress-free carbon atom, as in methane ( $109.4^\circ$ ), has been forced into a strained ring with a C—C—C bond angle of  $104^\circ$ , and the bonds (electron clouds) are not straight as shown in Figure 2 but rather are banana-shaped. The distance of the carbon atoms is 1.151 Å. The  $\angle\text{H—C—H}$  angle formed by the hydrogen atoms surrounding the carbon atoms is  $115.1^\circ$ . The length of the C—C bonds is shorter than in cyclohexane but still weaker than in cyclohexane.

**Figure 2:** Molecular structure of cyclopropane.

### 2.2.3 Thermodynamic Properties of Cyclopropane

Thermodynamic properties of cyclopropane are listed in Table 2.

**Table 2:** Thermodynamic properties of cyclopropane.

| Property                            | SI units                                  | Other units                                  | References |
|-------------------------------------|-------------------------------------------|----------------------------------------------|------------|
| Standard enthalpy of formation, gas | +53.3 kJ/mol                              | +12.74 kcal/mol                              | [17, 18]   |
| Heat capacity, liquid at 150 K      | 75.81 J mol <sup>-1</sup> K <sup>-1</sup> | 18.12 cal mol <sup>-1</sup> °C <sup>-1</sup> | [16]       |
| Heat capacity, liquid at 240 K      | 81.34 J mol <sup>-1</sup> K <sup>-1</sup> | 19.44 cal mol <sup>-1</sup> °C <sup>-1</sup> |            |
| Enthalpy of fusion                  | 5443 J/mol                                | 1301 cal/mol                                 |            |
| Enthalpy of vaporization at 240 K   | 20.054 kJ/mol                             | 4.793 ± 3 kcal/mol                           |            |
| Entropy, gas, at 298 K              | 237.8 J mol <sup>-1</sup> K <sup>-1</sup> | 56.84 cal mol <sup>-1</sup> °C <sup>-1</sup> |            |

Note: Molecular mass 42.0797 g/mol = 23.764 mol/kg

The enthalpy and entropy of cyclopropane were calculated from experimental pressure-volume-residual temperature data [21]. The heat capacity of the ideal gas cyclopropane in the range 291–458 K (525–825 °R) can be expressed by the following equation

$$c_p = 2.520225 + 9.055728 \times 10^{-3} T + 2.968219 \times 10^{-5} T^2 - 1.650501 \times 10^{-8} T^3$$

where  $c_p$  is the heat capacity in BTU lb<sup>-1</sup> °F<sup>-1</sup> and  $T$  is the temperature in °R.

## 2.3 Chemical Properties of Cyclopropane

The chemical properties of cyclopropane are quite different from those of the other cycloalkanes. Cyclopropane is thermally less stable and more reactive, very often resulting in ring opening.

### 2.4 Toxicity of Cyclopropane

Cyclopropane (in mixture with 15–30 vol.-% oxygen) had been used for anesthesia, but this application was quickly abandoned because of the explosivity of the mixture.

### 2.5 Flammability of Cyclopropane

The flammable range of cyclopropane in air with upward propagation is from 2.4 vol.-% to 10.4 vol.-% C<sub>3</sub>H<sub>6</sub>. The autoignition temperature in air is 768 K (495 °C).

### 3 Cyclopropane Derivatives – Polycyclic Isocyclic Hydrocarbons

The chemistry of cyclopropane and compounds containing cyclopropyl groups is of particular interest to all rocket propellant chemists [22].

In a study to prepare and purify 19 hydrocarbon derivatives of cyclopropane and evaluate them as rocket or air-breathing engine fuels, 13 of these hydrocarbons were synthesized for the first time [23]. In addition to the hydrocarbons, six cyclopropylcarbinols, five alkyl cyclopropyl ketones, three cyclopropyl chlorides, and one cyclopropanedicarboxylate were prepared as intermediates for subsequent syntheses. The melting points, boiling points, refractive indices, densities, and, in some instances, heats of combustion of both the hydrocarbon and non-hydrocarbon derivatives of cyclopropane were determined, including the very sharp IR spectra of each of the 34 cyclopropane compounds. The IR absorption bands characteristic of the cyclopropyl ring were identified. Many of the cyclopropane derivatives have bands at  $3.23 \pm 0.02 \mu\text{m}$  and at  $3.33 \pm 0.02 \mu\text{m}$ . Nearly all the cyclopropane derivatives showed strong absorption between  $9.7$  and  $9.8 \mu\text{m}$  and between  $11$  and  $12 \mu\text{m}$ . Some observations were made on the contribution of the cyclopropyl ring to the molecular refractions of cyclopropane compounds. A total of 12 cyclopropylalkenes and five cyclopropylalkanes were prepared from methyl cyclopropyl ketone. Vinylcyclopropane had a melting point of  $164 \text{ K}$  ( $-109^\circ\text{C}$ ), a boiling point of  $313 \text{ K}$  ( $40^\circ\text{C}$ ), a density of  $0.72105 \text{ g/cm}^3$ , and a refractive index of  $n_D^{20} = 1.4138$ .

Cyclopropyl derivatives carrying an energetic substituent such as a nitrile group or a vinyl group, have been evaluated as fuels for air-breathing engines [24].

Cyclopropyl compounds synthesized by cyclopropanation have high density and high energy caused by internal ring tension, which gives the molecule a high enthalpy of formation. Three different methods for cyclopropanation, i.e., conversion of a ring-contained  $\text{C}=\text{C}$  double bond to an external cyclopropane ring, were used for adding one or two cyclopropane rings to norbornene, norbornadiene, or dicyclopentadiene [25]. The volumetric heat of combustion of several of these compounds was higher than that of RJ-4 or JP-10 (Figure 3). For comparison, the heat of combustion of JP-10 is  $42.1 \text{ MJ/kg}$ .

**Figure 3:** Heat of combustion of cyclopropane derivatives. (Based on data from [25].)

### 3.1 Bicyclopropyl and Spiropentane

Other energetic fuels of interest are cyclopropyl cyclopropane (“bicyclopropane,” “bicyclopropyl”) and di(cyclopropyl)methane. Strained ring hydrocarbons with two cyclopropane rings in the molecule can be formed by either connecting two cyclopropanes through an external C—C bond or by sharing a carbon atom.

Bicyclopropyl,  $C_6H_{10}$ , CAS RN [5685-46-1], has a molecular mass of 82.1436 g/mol, a melting point of 191 K ( $-82^\circ\text{C}$ ), a boiling point at 760 mm Hg of 349 K ( $76^\circ\text{C}$ ), a refractive index  $n_D^{20}$  of 1.4239, a density of  $0.7898\text{ g/cm}^3$ , an enthalpy of formation (liquid) of  $96.0 \pm 3.8\text{ kJ/mol}$ , and a net heat of combustion of  $3703\text{ kJ/mol}$  ( $885\text{ kcal/mol}$ ). Solid bicyclopropyl has a density of  $1.035\text{ g/cm}^3$  at 173 K [26]. The central C—C bond in bicyclopropyl is shorter than a typical aliphatic C—C bond, more like a single bond in a conjugated system.

Spiropentane,  $C_5H_8$ , CAS RN [157-40-4], has a freezing point of 168 K ( $-105^\circ\text{C}$ ), a boiling point at 760 mm Hg of 311.9 K ( $38.8^\circ\text{C}$ ), a density of  $0.7551\text{ g/cm}^3$ , a heat of fusion of  $6.43\text{ kJ/mol}$ , a heat of vaporization of  $27.7\text{ kJ/mol}$ , and a refractive index of  $n_D^{20} = 1.4122$  [27].

Bicyclopropylidene, made up from two cyclopropane rings linked by a C=C double bond, is a particularly strained derivative of cyclopropane. It undergoes a thermal rearrangement and dimerization [28, 29]. Bicyclopropylidene was tested in a 220-N (50-lb<sub>f</sub>) rocket engine with LOX as the oxidizer in a side-by-side test in comparison to RP-1 [30]. The density is 1.5% greater than that of RP-1, and the  $I_{sp}$  is approximately 2 to 4% better than that of RP-1. However, the volume benefit is negative. The boiling point of bicyclopropylidene is 374 K ( $101^\circ\text{C}$ ) at 101 kPa. The freezing point is 261 K ( $-12^\circ\text{C}$ ). The density is  $0.8454\text{ g/cm}^3$  at 293 K. The vapor pressure is 11.4 kPa at 298 K ( $85.9\text{ mm Hg}$  at  $25^\circ\text{C}$ ). The kinetic viscosity is  $0.808\text{ cSt}$  at 313 K ( $40^\circ\text{C}$ ). The flash point is  $266.7\text{ K}$  ( $-6.4^\circ\text{C}$ ). The standard enthalpy of formation is  $+264\text{ kJ/mol}$  ( $+63.1\text{ kcal/mol}$ ). The heat of combustion is  $44.4\text{ MJ/kg}$  ( $19113\text{ BTU/lb}$ ).

A laboratory-scale flow reactor was developed to subject small amounts (approximately 1 mL) of deoxygenated fuels to controlled conditions of temperature and residence-time-at-temperature at constant pressure (34 atm) in the liquid or supercritical phase [31]. The thermal stability of the parent material and the thermal fragmentation products of each fuel were measured. Some of the candidate materials tested (quadricyclane and bicyclopropylidene) showed only marginal thermal stability, with major decomposition already occurring before 673 K ( $400^\circ\text{C}$ ) ( $\sim 3\text{ s}$

residence time). Other fuels (JP-10, RP-1, RG-1, RJ-6, and RJ-7) showed excellent thermal stability with little decomposition even at 873 K (600 °C). Results showed the pyrolytic stability of candidate materials relative to each other and provided insights into the mechanisms of thermal decomposition for specific fuel candidates.

### 3.2 Ivyanes and Triangulanes

Hydrocarbons with cyclopropane rings in the molecules, called ivyanes, with several cyclopropane rings attached to each other, were proposed as fuels for hybrid rockets [32, 33].

Practical synthesis of the first six members of the ivyane (1,1-oligocyclopropane) family of energetic hydrocarbons was achieved from the cross-conjugated polyenes known as dendralenes. Dendralenes are unsaturated hydrocarbons with multiple *exo*-ene double bonds in their side chains. The C=C double bonds can be converted to connected cyclopropane rings with three to eight cyclopropane rings in the molecule [34].

These molecules may have helical conformations in both the solid state and in solution. Ivyanes have the highest experimental heats of combustion recorded for any hydrocarbon. Ring-opening reactions of ivyanes are common. [3]- to [6]-ivyanes are oils at ambient temperature, but [7]- and [8]-ivyanes are solids. The ivyanes are kinetically stable up to moderate temperatures. [8]-ivyane, for example, melts at 368 K (95 °C) in air without significant decomposition, and [6]-ivyane is kinetically stable to about 473 K (200 °C). The heat of combustion of [6]-ivyane was found to be  $50.8 \pm 2.5 \text{ MJ/kg} = 12.3 \pm 0.6 \text{ MJ/mol}$ , which is one of the highest reported for any hydrocarbon and is significantly higher than that of cubane. The molar heat of combustion of [6]-ivyane is roughly six times that of cyclopropane (2.1 MJ/mol).

Highly strained oligospirocyclopropane systems would make good fuels, but they are difficult to obtain [35, 36]. Ivyanes can form not only linear chains but also ring structures. There are numerous exotic two-dimensional (2D) and three-dimensional

(3D) molecule structures that can incorporate three-ring and four-ring elements [37]. These include [1.1.1]propellane, prismane, cubane, bicyclopropylidene, triangulanes, and tetrahedrane, but some of these have not yet been isolated [38]. The molecules described in the following are exotic examples of unique molecular structures; some look like atomic artwork.

These compounds have been obtained only in milligram quantities, so they will never be used as rocket propellants. The enthalpies of formation of trispiro[2.0.0.2.1.1]-nonane (3), [3]rotane (4), *n*-heptyl[3]rotane (6), spiro-[2.3]hexane, and isomeric dispiro[2.0.2.2]octane (8) and dispiro[2.1.2.1]octane (9), as well as [4]rotane (10), were determined by measuring their heats of combustion in a microcalorimeter [39]. The enthalpy of formation values and the strain energies derived from them were compared with values from quantum mechanical calculations. The results confirmed previously reported theoretical and experimental values for spiropentane and established an additivity scheme for strain energies in different types of [*n*]triangulanes, with an excessive strain energy increment of 36 kJ/mol (8.6 kcal/mol) per spiro carbon atom. A simple additivity of strain energies without an excess increment can be employed for spirocyclopropanated cyclobutanes as well as for larger rings including [*n*]rotanes ( $n > 4$ ).

There are many spirocyclic compounds that have high heats of combustion and are candidates for high-energy fuels. These can either be synthesized in the lab or their performance can be predicted by computational methods [40].

### 3.3 Syntin (1-Methyl-1,2-dicyclopropylcyclopropane)

Syntin,  $C_{10}H_{16}$ , 1-methyl-1,2-dicyclopropylcyclopropane, 1'-methyl-1,1':2',1''-tercyclopropane, synthin, tsycklin, cyclane, CAS RN [93223-46-2], is a synthetic hydrocarbon and was used as a rocket fuel in the former Soviet Union. Syntin is a mixture of four possible *cis* and *trans* isomers. It has a density of  $0.851\text{ g/cm}^3$  and a boiling point of  $431\text{ K}$  ( $158^\circ\text{C}$ ). Because of the presence of three strained cyclopropane rings in the molecule, the compound has a very high positive enthalpy of formation:  $\Delta H_f^\circ(\text{L}) = +133\text{ kJ/mol}$  ( $+980\text{ kJ/kg} = +234\text{ cal/g}$ ), the average value for the isomeric mixture, bringing additional energy during the combustion process. Thus, it has advantages over the traditional hydrocarbon fuels, such as RP-1, because of higher density, lower viscosity, and higher heat of combustion. Syntin was used in the Soviet Union, and later Russia, in the 1980s and 1990s as fuel for the Soyuz-U2 rocket. It was first synthesized in the USSR in the 1960s and was brought to mass production in the 1970s. It was prepared in a multi-step synthetic process from common hydrocarbon sources [41, 42].

The production of this fuel is very expensive, and eventually it was halted.

Syntin was originally used on the Buran reaction control system (RCS)/orbital maneuvering system (OMS), which evolved to be used on the 11D58S (also known as RD-58S) engine on the Proton DM upper stage and in the second-stage engine of the Soyuz-U2 rocket [43]. It is reportedly denser than standard RG-1 (or RP-1) and provides a performance boost of approximately 8–10 s of vacuum-specific impulse. In 1996, the Russians discontinued production of Syntin, citing its high production cost and stating that they had sufficient stockpiles to meet their commercial launch needs until the DM stage was replaced by the  $LO_2/LH_2$  KM stage (powered by the RD-56M) and the  $N_2O_4/UDMH$  Briz (Breeze) upper stage (powered by the S5.98M engine). The termination of syntin production also forced the abandonment of the Soyuz 11A511U2 “Rus” booster, an updated version of the standard Soyuz 11A511U booster, which used syntin instead of standard kerosene in the first stage for launch of premium reconnaissance satellites and manned payloads that required extra payload performance.

Syntin can be analyzed by chromatography in combination with mass spectrometry (MS) [44]. As an example of gas chromatography (GC)–MS analysis capabilities, the total ion current chromatogram of a syntin propellant sample containing other hydrocarbon impurities was shown in [44].

### 3.4 Alkylcyclopropanes

Alkylcyclopropanes combine the energetic ring structure of cyclopropane with the favorable hydrogen content of alkanes in one molecule. Table 3 lists physical properties of alkylcycloalkanes [45].

**Table 3:** Physical properties of alkylcyclopropanes.

| Compound                               | Density at 298 K  | Heat capacity at 298 K            |                                      | Boiling point |       |
|----------------------------------------|-------------------|-----------------------------------|--------------------------------------|---------------|-------|
|                                        | g/cm <sup>3</sup> | J g <sup>-1</sup> K <sup>-1</sup> | cal g <sup>-1</sup> °C <sup>-1</sup> | K             | °C    |
| Methylcyclopropane                     | 0.634             | 2.30                              | 0.55                                 | —             | —     |
| Ethylcyclopropane                      | 0.679             | 2.26                              | 0.54                                 | 309.08        | 35.93 |
| <i>cis</i> -1,2-Dimethylcyclopropane   | 0.6889            | 2.26                              | 0.54                                 | 310.18        | 37.03 |
| <i>trans</i> -1,2-Dimethylcyclopropane | 0.6648            | 2.26                              | 0.54                                 | 301.36        | 28.21 |
| 1,1,2-Trimethylcyclopropane            | 0.6897            | 2.22                              | 0.53                                 | 325.6         | 52.44 |
| 1,1,2,2-Tetramethylcyclopropane        | 0.702             | 2.18                              | 0.52                                 | 344           | 71    |

Data source: [45]

The enthalpies of combustion of six alkylcyclopropanes were measured by oxygen-bomb combustion calorimetry, and values of the enthalpies of formation of the liquids were derived therefrom. Table 4 lists the constant volume energy of combustion, the constant pressure enthalpy of combustion, and the standard enthalpy of formation of liquid alkylcyclopropanes.

1,3,3-trimethylcyclopropene is very sensitive to oxygen in air, causing formation of a thick polymeric gum [46]. This energetic fuel can be dissolved in RP-1.

### 3.5 Alkenyl- and Alkynyl-cyclopropanes

Another cyclopropane derivative considered as rocket propellant is ECP dimer, ethynyl cyclopropyl dimer, 1,4-dicyclopropyl-1,3-butadiyne. It has been considered as a bipropellant fuel with HTP or PERSOL-2 as the oxidizer [47].

**Table 4:** Thermodynamic properties of liquid alkylcyclopropanes at 298.15 K.

| Compound                                    | $\Delta E_c^{298}$  |                       | $\Delta H_c^{298}$  |                       | $\Delta H_f^{298}$  |                      |
|---------------------------------------------|---------------------|-----------------------|---------------------|-----------------------|---------------------|----------------------|

Data source: [45]

Ethynylcyclopropane, cyclopropylacetylene,  $C_5H_6$ , CAS RN [6746-94-7], has been considered as a high-energy bipropellant fuel [48]. Ethynylcyclopropane can be prepared from (1,1-dimethoxyethyl)cyclopropane by a two-stage elimination of methanol [49]. The freezing point of ethynylcyclopropane is less than 248 K (less than  $-25^\circ\text{C}$ ). The boiling point of ethynylcyclopropane is 325–338 K ( $52$ – $65^\circ\text{C}$ ). The density is  $0.7801\text{ g/cm}^3$ . The vapor pressure is 34.1 kPa. The enthalpy of formation of cyclopropyl methyl acetylene is  $+218\text{ kJ/mol}$  ( $+52.0\text{ kcal/mol}$ ). Ethenylcyclopropane (vinylcyclopropane, cyclopropylethylene) and cyclopropylcyanide have been considered as energetic fuels [24].

## 4 Cyclobutane and Cyclobutane Derivatives

Cyclobutane, also known as cyclotetramethylene,  $C_4H_8$ , CAS RN [287-23-0] is a cycloaliphatic hydrocarbon and part of the skeleton of many naturally occurring chemicals. This is surprising because the four-membered ring is still strained and not easy to form. There are no known applications of cyclobutane or cyclobutane derivatives as rocket propellants. Many polycyclic hydrocarbons contain a four-membered ring, but that does not make them cyclobutane derivatives.

## 4.1 Preparation of Cyclobutane

Cyclobutane can be prepared by dehalogenation of 1,4-dihalobutanes with zinc or magnesium [50]. Ethylene may dimerize under the influence of ultraviolet (UV) light.

## 4.2 Physical Properties of Cyclobutane

Physical properties of cyclobutane are summarized in Table 5.

**Table 5:** Physical properties of cyclobutane.

| Property                                                         | SI units                | Other units          | References |
|------------------------------------------------------------------|-------------------------|----------------------|------------|
| Molecular mass                                                   | 56.1063 g/mol           | 17.8233 mol/kg       | [17]       |

| Enthalpy of vaporization at normal boiling point                 | 23.92 kJ/mol            | 5.72 kcal/mol        | [51]       |

The vapor pressure of cyclobutane in the range 213–285 K can be calculated from an Antoine equation with the coefficients

$$\log P = 4.07143 - [1038.009 / (T - 30.334)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. See also [50].

The unusually high enthalpy of formation of cyclobutane and many of its derivatives can be explained by strain energy [52]. The term strain energy is usually considered relative to a theoretical unstrained state of the molecule. The strain energy can be calculated from the difference between the experimentally determined enthalpy of formation and the enthalpy of formation predicted from additive behavior of unstrained bonds:

$$\text{Strain energy} = \Delta H_{f,\text{exp.}} - \Delta H_{f,\text{calc.}}$$

The standard enthalpy of formation of cyclobutylacetylene is +236 kJ/mol (+56.3 kcal/mol).

### 4.3 Molecular Structure of Cyclobutane

The molecular structure of cyclobutane is that of a four-membered ring, but the ring is not flat (Figure 4). The cyclobutane ring is strained, and the C—C—C bond angle is different from the unstrained tetrahedral angle of  $109.45^\circ$ . The bond angles are not  $90^\circ$  as in a perfect flat square because the bonds are banana-shaped and the four-membered ring is not flat. One of the carbon atoms sticks out and makes a  $25^\circ$  angle with the plane formed by the other three carbons. Cyclobutane is a molecule that undergoes inversion, which may split some absorption bands. IR, Raman, and electron diffraction spectra suggest that the equilibrium configuration of cyclobutane is  $D_{2d}$  symmetry and that the barrier hindering inversion is sufficiently low so that even at room temperature, an appreciable number of molecules obey  $D_{4h}$  selection rules [53].

**Figure 4:** Molecular structure of cyclobutane.

Another strained multi-ring compound would be [1.1.0]-bicyclobutane, a cyclobutane in which opposite corners are connected by an internal C—C bond [54–56]. This molecule could also be described as the combination of two cyclopropane rings that share a base of the triangles.

An even more strained ring molecule is [1.1.1]propellane, in which not just two but three cyclopropyl rings share a common side of three triangles.

## 5 Cyclopentane and Cyclopentane Derivatives

Cyclopentane,  $C_5H_{10}$ , CAS RN [287-92-3], in small quantities may be found in cracked petroleum products along with cyclopentadiene. It is not used as a rocket propellant in the pure state.

## 5.1 Physical Properties of Cyclopentane

Physical properties of cyclopentane are summarized in Table 6.

**Table 6:** Physical properties of cyclopentane.

| Property                                                         | SI units                                       | Other units                                         | References |

| Enthalpy of formation, liquid under pressure, $\Delta H_f^{298}$ | −105.6 ± 1.8 kJ/mol                            | −25.24 ± 0.43 kcal/mol                              |            |
| Enthalpy of vaporization at 322.4 K                              | 27.3 kJ/mol                                    | 6.52 kcal/mol                                       | [51]       |
| Enthalpy of fusion at 179.7 K                                    | 0.6 kJ/mol                                     | 0.143 kcal/mol                                      | [17]       |
| Critical temperature                                             | 511.7 ± 0.2 K                                  | 238.6 °C                                            |            |
| Critical pressure                                                | 45.1 ± 0.4 bar                                 | 654 psia                                            |            |
| Critical volume                                                  | 3.85 ± 0.04 mol/L                              | —                                                   |            |

The vapor pressure of cyclopentane in the range 288.86–323.18 K can be calculated from the Antoine equation

$$\log P = A - [B/(T + C)] = 4.00288 - [1119.208/(T - 42.412)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

## 5.2 Physical Properties of Cyclopentadiene

Cyclopentadiene, C<sub>5</sub>H<sub>6</sub>, CAS RN [542-92-7], is an important raw material in the synthesis of dicyclopentadiene and the intermediates for the synthesis of JP-10. Cyclopentadiene is a byproduct of petroleum refining [58, 59]. Cyclopentadiene and dicyclopentadiene

tadiene (DCPD) occur as by-products in the steam-cracking process in ethylene plants and are the major ingredients in the production of hydrocarbon resins, unsaturated polyester resins, elastomers, pesticides, flame retardants, and many specialty chemicals. Cyclopentadiene dimerizes readily, via the Diels-Alder mechanism, to DCPD at ambient conditions. The dimerization is highly exothermic. Because of its reactivity, cyclopentadiene is normally available only in the stable dimer form. Pure cyclopentadiene can be produced by the thermal cracking of DCPD at a temperature near the normal boiling point of DCPD. Cyclopentadiene traces may be present as incomplete conversion or depolymerization products of JP-10. Physical properties of cyclopentadiene are summarized in Table 7.

**Table 7:** Physical properties of cyclopentadiene.

| Property                                                         | SI units                                         | Other units                                                       | References |

## 6 Cyclohexane

Cyclohexane,  $\text{C}_6\text{H}_{12}$ , CAS RN [110-82-7], also known as hexahydrobenzene, hexamethylene, is the main representative of the family of cycloalkyl hydrocarbons and the most readily available chemical in this group [60]. The cyclohexyl ring can be found in many natural and synthetic fuel products. There are numerous derivatives of cyclohexane in use in various functions in rocket propellants, and cyclohexane is a constituent of many fuel mixtures derived from petroleum refining. The only other six-ring compound of more importance is benzene, which can be obtained by dehydrogenation of cyclohexane.

## 6.1 Production of Cyclohexane

Cyclohexane is produced by reduction of benzene.

## 6.2 Physical Properties of Cyclohexane

### 6.2.1 Mechanical and Thermal Properties of Cyclohexane

Physical properties of cyclohexane are listed in Table 8.

**Table 8:** Physical properties of cyclohexane.

| Property                                                  | SI units                                            | Other units                                             | References |

The vapor pressure of cyclohexane can be calculated from the Antoine equation

$$\log P = A - B/(T + C) = 5.9655598 - [1200.428/(T - 50.6773)]$$

where  $P$  is the vapor pressure in kPa and  $T$  is the temperature in kelvin [62]. The data in Table 9 were calculated with this equation.

**Table 9:** Vapor pressure of cyclohexane.

| Temperature<br>K | Vapor pressure |       |
|------------------|----------------|-------|
|                  | kPa            | mm Hg |
| 273              | 3.7            | 27.6  |
| 280              | 5.4            | 40.4  |
| 290              | 8.9            | 66.8  |
| 293              | 10.3           | 77.1  |
| 298              | 12.9           | 97.1  |
| 300              | 14.2           | 106   |
| 310              | 21.7           | 163   |
| 320              | 32.2           | 242   |
| 330              | 46.6           | 349   |
| 340              | 65.5           | 492   |
| 350              | 90.2           | 676   |
| 353.9            | 101.5          | 762   |

A wide range of reference equations for the thermal conductivity of cyclohexane as a function of temperature and density was based in part on a body of experimental literature data that had been critically assessed for internal consistency and for agreement with theory whenever possible [63]. Uncertainties in the critical region were significant, since the thermal conductivity approaches infinity at the critical point and is very sensitive to small changes in density.

### 6.2.2 Molecular Structure of Cyclohexane

The symmetrical six-membered ring structure of cyclohexane is the ideal precursor for stable aromatic six-membered rings, and many pyrolytic and dehydrogenating conversions of cyclohexane and cyclohexane derivatives end up with aromatic structures that are favored from a standpoint of energy.

Electron diffraction studies, dynamic nuclear magnetic resonance (NMR) spectroscopy, analysis of vibrational spectra, and theoretical calculations indicate that the chair conformation ( $D_{3d}$  symmetry) is the most stable form of cyclohexane. The strain-energy calculations showed that there are also two other conformations, twist-boat ( $D_2$  symmetry) and boat ( $C_2$  symmetry), with an energy of about 20–25 kJ/mol above that of the chair form. The twist-boat and boat forms can interconvert by pseudo-rotation. Calculations have suggested that the twist-boat forms are at the minima of the pseudo-rotation path and that the boats are transition states about 4 kJ/mol above the twist boats.

Chair Conformation

Boat Conformation

### 6.3 Chemical Properties of Cyclohexane

There are numerous publications about the dehydrogenation of cyclohexane (not included here for lack of space), and many of those relate to the dehydrogenation of methylcyclohexane, using the same catalysts and the same methods of investigation. The dehydrogenation of methylcyclohexane has more practical importance as a step for endothermic fuels than the dehydrogenation of cyclohexane.

The reaction mechanisms for thermal decomposition of cyclohexane in the gas phase have been investigated using quantum chemical calculations and transition-state theory [64]. The predicted rate constants and kinetic parameters in the modified Arrhenius equation form were in good agreement with data available from the literature.

## 7 Methylcyclohexane

Methylcyclohexane,  $C_7H_{14}$ , CAS RN [108-87-2], is rarely used as such in the pure state, but it is a constituent of JP-9. Methylcyclohexane (MCH) has been selected as the constituent of some surrogate fuel mixtures. It has disadvantages in some high-speed air-breathing vehicle applications because of its relatively high vapor pressure, low density, and comparatively low volumetric heat of combustion.

### 7.1 Production of Methylcyclohexane

Methylcyclohexane can be prepared by reduction of toluene. MCH and decahydronaphthalene (decalin) are potential fuels that could provide the heat sink that is required for high-Mach air-breathing vehicles. At the beginning of these programs, domestic suppliers of methylcyclohexane and decalin were identified, and production rates were determined. Two producers of MCH and one producer of decalin were identified, but production capacity of these materials was limited at that time, and the

materials were sold only as specialty chemicals with an associated high cost. Technologies were sought to allow expansion of production facilities and to reduce the cost of MCH.

## 7.2 Physical Properties of Methylcyclohexane

Physical properties of methylcyclohexane are listed in Table 10.

**Table 10:** Physical properties of methylcyclohexane.

| Critical density                                          | 267.07 kg/m <sup>3</sup>                                                             | —                                                                         |            |

Physical and thermochemical properties of pure MCH were measured so that it could be used as a constituent of surrogate fuel mixtures. This was done as part of an effort to develop surrogate fuels to represent the thermophysical properties of aviation kerosenes described under the umbrella names of Jet-A and JP-8 [71].

### 7.2.1 Density of Methylcyclohexane

The density, velocity of sound, and adiabatic compressibility of MCH and propylcyclohexane were measured over the temperature range 278–343 K. The data are listed in Table 11.

**Table 11:** Density, velocity of sound, and adiabatic compressibility of methylcyclohexane and propylcyclohexane.

| Temperature<br>K | Methylcyclohexane             |                                           |                                                   | Propylcyclohexane             |                                           |                                                   |

Data source: [71]

The density of methylcyclohexane can be calculated from the equation

$$\rho = 0.80217 - 0.0004830t$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $t$  is the temperature in  $^{\circ}\text{F}$  [72].

### 7.2.2 Vapor Pressure of Methylcyclohexane

The vapor pressure of MCH can be calculated from the Antoine equation

$$\log P = A - B/(T + C) = 5.9140199 - [1250.905/(T - 54.0054)]$$

where  $P$  is the vapor pressure in kPa and  $T$  is the temperature in kelvin [62]. The data in Table 12 were calculated with this equation.

The density and velocity of sound of liquid MCH and propylcyclohexane from 270 to 470 K with pressures to 40 MPa were measured with two vibrating-tube densime-

**Table 12:** Vapor pressure of methylcyclohexane.

| Temperature<br>K | Vapor pressure |       |
|------------------|----------------|-------|
|                  | kPa            | mm Hg |
| 273              | 1.6            | 12    |
| 280              | 2.4            | 18    |
| 290              | 4.1            | 31    |
| 298              | 6.1            | 46    |
| 300              | 6.7            | 51    |
| 310              | 10.7           | 80    |
| 320              | 16.3           | 122   |
| 330              | 24.1           | 181   |
| 340              | 34.7           | 260   |
| 350              | 48.7           | 366   |
| 360              | 67.0           | 503   |
| 370              | 90.2           | 677   |
| 374              | 101.1          | 759   |

Data source: [62]

ters and a time-of-flight method, respectively [73]. Comparisons with literature data showed good agreement in overlapping ranges. See also [74].

The graphs in Figures 5 and 6 are based on numerical data first published in [68] and then graphed by other users. Vapor pressures of methylcyclohexane over two different temperature ranges are illustrated in Figures 5 and 6.

**Figure 5:** Vapor pressure of methylcyclohexane (low temperature range). (Chart created by Schmidt 2020 based on data from [68].)

**Figure 6:** Vapor pressure of methylcyclohexane (high temperature range). (Chart created by Schmidt 2020 based on data from [68].)

### 7.2.3 Viscosity of Methylcyclohexane

The dynamic viscosity of liquid MCH based on data from [75] is illustrated in Figure 7.

**Figure 7:** Dynamic viscosity of liquid methylcyclohexane. (Chart created by Schmidt 2020 based on data from [75].)

The viscosities of MCH and propylcyclohexane were measured between 300 and 360 K [71]. The results are listed in Table 13. The kinematic viscosity and density of MCH were measured in the temperature range of 219 to 341 K (−65 to +155 °F), as listed in Table 14.

**Table 13:** Viscosities of methylcyclohexane and propylcyclohexane.

| Methylcyclohexane |                                                    | Propylcyclohexane |                                                    |

#### 7.2.4 Thermal Conductivity of Methylcyclohexane

The thermal conductivities of MCH and propylcyclohexane liquid and vapor were measured covering a temperature range of 300 to 600 K and a pressure range of 0.1 to 60 MPa and were used to develop correlations for the thermal conductivity [69]. The data included a contribution due to thermal radiation that increased in proportion to temperature cubed up to an estimated value from 2 to 3% near 600 K. Two graphs in this publication show the thermal conductivities of the alkylcyclohexanes as a function of density rather than as a function of temperature. That format of data representation may be of scientific interest, but the more practical graphs with properties shown as a function of temperature or pressure are missing. The thermal conductivity of liquid MCH at 300 K is  $0.106 \text{ W m}^{-1} \text{ K}^{-1}$  at a density of  $763 \text{ kg/m}^3$ . The thermal conductivity of liquid MCH at 450 K under 50 MPa pressure is  $0.099 \text{ W m}^{-1} \text{ K}^{-1}$  at a density of  $702 \text{ kg/m}^3$ .

The thermal conductivity of MCH and propylcyclohexane at temperatures from 300 to 595 K and pressures up to 60 MPa was again measured and resulted in a second set of data, but the results were displayed only as a function of density instead of as a function of temperature [71].

### 7.2.5 Surface Tension of Methylcyclohexane

The surface tension of MCH at 298 K is 23.42 mN/m [61]. The density of the same sample was 0.76499 g/cm<sup>3</sup>. The surface tension of MCH is 32.843, 30.806, 24.465, and 19.519 dyn/cm at 219, 239, 295, and 343 K (−65, −30, +72, and +158 °F), respectively [72].

### 7.2.6 Thermodynamic Properties of Methylcyclohexane

The isobaric heat capacity data of MCH in the temperature range of 298.1 to 775.4 K and the pressure range of 3.5 to 5 MPa was measured by a mixing technique [76]. In the low-temperature region, the isobaric heat capacity of MCH increased gently with increasing temperature. At the pseudo-critical region, the isobaric heat capacity increased sharply to a peak value and then decreased dramatically in a nearly symmetrical way.

The heat capacity of MCH at 233, 293, and 339 K (−40, +20, and +66 °C) is, respectively, 1.653, 1.929, and 2.171 J g<sup>−1</sup> K<sup>−1</sup> (0.395, 0.461, and 0.519 cal g<sup>−1</sup> °C<sup>−1</sup>) (average of five consecutive tests) [72].

Thermodynamic properties of MCH and several other alkylcycloalkanes are summarized in Table 15. The gross heat of combustion of MCH is 19989 BTU/lb = 11105 cal/g, and the net heat of combustion is 18700 BTU/lb = 10389 cal/g (average of two repeated tests) [72]. See also [77].

The enthalpy of vaporization of MCH as a function of temperature in the range 298–374 K can be calculated from the equation

$$\Delta H_v = A \exp(-\beta T_r)(1 - T_r)^\beta$$

where  $T_r$  is the reduced temperature  $T_r = T/T_c$  with  $T_c = 572.1$  K,  $\Delta H_v$  is the enthalpy of vaporization at saturation pressure in kJ/mol, and  $T$  is the temperature in kelvin.  $A$  and  $\beta$  are constants, with  $A = 49.56$  and  $\beta = 0.2685$ .

### 7.2.7 Electrical Properties of Methylcyclohexane

The dielectric constant of methylcyclohexane is 2.129, 2.055, 2.024, and 1.960 at 219, 273, 295, and 342 K (−65, 32, 72.5, and 156 °F), respectively [72].

**Table 15:** Thermodynamic properties of alkylcycloalkanes.

| Compound                     | Heat of combustion at 298 K (25 °C) |                   |                 |                   | Enthalpy of formation at 298 K (25 °C) |                  |                 |                  |

### 7.3 Chemical Properties of Methylcyclohexane

For its application as a fuel in air-breathing engines, the most important chemical property of MCH is the endothermicity of its thermal decomposition, making it a good coolant for hot parts of the engine or leading edges of hypersonic aircraft. The evaluation of MCH as an endothermic fuel in comparison to decalin or bicyclohexyl is discussed in Section 2.2.1.3 on endothermic fuels in chapter “Hydrocarbons.”

The maximum-cruise Mach capability of most endothermic fuels was found to be Mach 6. Significant increases in fuel heat capacity would be necessary to increase the maximum-cruise Mach number. At Mach 7, the propulsive energy in methylcyclohexane was not sufficient to complete the mission range using turboramjets.

The addition of methyl groups to the cycloalkane ring may decrease the stability of the catalyst system used to effect dehydrogenation. The addition of methyl groups may improve equilibrium conversion at lower temperatures.

### 7.3.1 Thermal Decomposition of Methylcyclohexane

The vapor-phase thermal decomposition of four jet fuel candidates (MCH, toluene, *trans*-decalin, and naphthalene) has been measured under precisely controlled conditions of reaction atmosphere, exposure temperature, and residence time at atmospheric pressure and temperatures from 300 to 1050 K [78]. Differences in fuel thermal decomposition were analyzed with respect to molecular structure and thermochemical bond energy analysis. The thermal decomposition data for these compounds were used to evaluate their potential heat-sink capacities. In a separate but related study, the gas-phase thermal degradation behavior of MCH was examined for a broad range of reaction conditions. The results indicated that removal of oxygen from the fuel-handling system and a reduction in high-temperature exposure time will greatly enhance the fuel's gas-phase stability.

The kinetics of thermal unimolecular decomposition of MCH were studied at temperatures in the range 861–1218 K using the technique of very-low-pressure pyrolysis (VLPP) [79]. Multiple reaction pathways and secondary decomposition of primary products resulted in a complex array of reaction products. VLPP rate data (fall-off regime) were obtained for the overall decompositions and interpreted via the application of Rice-Ramsperger-Kassel-Marcus (RRKM) theory. The data for methylcyclopentane and methylcyclohexane were interpreted in terms of ring-opening bond fission pathways and bond fission to methyl and cycloalkyl radicals. By selecting Arrhenius parameters consistent with the analogous pathways in open-chain alkanes, a good fit to the overall decomposition was obtained. The VLPP data were consistent with the following high-pressure rate expression (at  $T = 1100$  K) for the dominant primary reaction channel of ring opening adjacent to the substituent group:

$$\log k = (16.4 \pm 0.3) - (341 \pm 10)/\theta$$

where  $k$  is the rate constant in  $\text{s}^{-1}$  and  $\theta = 2.303RT \text{ kJ/mol}$ .

Methylcyclohexane was an essential part of the U.S. Air Force endothermic fuel program. Besides methylcyclohexane, multi-ringed hydrocarbons such as methyldecalin were evaluated as endothermic fuels.

In flight vehicles, the cross-section and aerodynamic drag can be reduced if the fuel has a high density. The search was on for high-density endothermic fuel systems. Additives and impurities have a pronounced effect on the rate of methylcyclohexane pyrolytic dehydrogenation. Cycloalkanes are the preferred endothermic fuels. See also [80].

High-temperature (1050–1200 K) pyrolysis studies of pure methylcyclohexane and oxidation studies of pure methylcyclohexane and methylcyclohexane/toluene blends were performed in a turbulent flow reactor [81]. Decomposition rates were reported at four temperatures between 1058 and 1192 K and at 1 atm, while fuel and ethene time histories were reported only at 1155 K. Ethene, 1,3-butadiene, methane, and propene were found to be the major intermediates produced by

methylcyclohexane pyrolysis. Oxidation of methylcyclohexane also produced the same intermediates. As expected, the observed oxidation reaction rates were faster than the pyrolysis reaction rates.

Pyrolysis of MCH has been investigated in a tubular reactor at atmospheric pressure in the temperature range 953–1073 K [82]. Using non-linear regression, the overall decomposition was found to be approximately first order, with a pre-exponential factor and activation energy of  $A = 1.71 \times 10^{11} \text{ s}^{-1}$  and  $E_{\text{act}} = 209.0 \text{ kJ/mol}$ . The experimental product yields and rates of conversion could be satisfactorily simulated using a molecular model consisting of an overall primary reaction and 24 secondary reactions.

Methylcyclohexane decomposition studies and analysis of the resulting products were carried out in non-pre-mixed air/methane flames at atmospheric pressure. The height above the burner was set such that the temperatures studied were near 1400 K [83]. The observed hydrocarbon products indicated that the specific dissociation pathways for the cycloalkanes were ring-opening isomerization to alkenes. All of the cycloalkanes produced similar distributions of aromatic hydrocarbons, which showed that they formed aromatics by addition reactions between their aliphatic decomposition products, not by direct dehydrogenation of their alkyl rings. Dimethylcyclohexanes produced more benzene than MCH did. The benzene production from MCH was comparable to that from the most-branched heptane isomer (2,3,3-trimethylbutane), which indicated that the cycloalkane portion of practical fuels will have a proportionately greater effect on soot production than the non-cyclic alkane portion.

A detailed kinetic investigation of the dehydrogenation of MCH over a wide range of operating conditions was conducted as part of an evaluation of MCH as a reversible hydrogen storage medium for on-board use of hydrogen in earthbound vehicles where the dehydrogenated product (mostly toluene) would be recycled to a hydrogenation station [65, 84]. The reaction kinetics were incorporated into a 2D pseudo-homogeneous model to predict observed longitudinal temperature profiles in reactors. Kinetic experiments were performed in a laboratory fixed-bed tubular reactor with a 1.0 mass-% Pt/Al<sub>2</sub>O<sub>3</sub> catalyst. The dehydrogenation of MCH is very selective toward toluene. As well as the main product toluene, a number of condensable by-products were also identified. Benzene, cyclohexane, and ring-closed products (ethylcyclopentane and dimethylcyclopentanes) were the major by-products [85]. See also [86].

Coke deposition during thermal decomposition of MCH may foul catalysts, clog orifices, and impede heat transfer through reactor walls [87]. An abundance of alkyl-substituted C<sub>5</sub> ring hydrocarbons caused the formation of polycyclic aromatic hydrocarbons, which were precursors for coke under supercritical conditions.

Monoalkylcyclohexanes are some of the typical constituents in certain jet fuels. As the first step to study the combustion chemistry of monoalkylcyclohexanes, the unimolecular reactions of MCH were investigated by both theoretical calculations and

experimental measurements for MCH pyrolysis and flames [88]. The temperature- and pressure-dependent kinetics of unimolecular reactions of MCH, including its dissociation and isomerization channels, were computed by high-level quantum chemical calculations, which also revealed the competitive relationship between the two reaction channels. The theoretical predictions were compared to the experimental observations, including species identification, measured by photoionization efficiency spectra. The unimolecular reaction mechanism and corresponding temperature- and pressure-dependent rate constants provided a useful reference for exploring the combustion chemistry of cyclohexanes by kinetic modeling.

A kinetic model consisting of 1216 free-radical and 87 molecular reactions and implying 239 species was developed to describe the thermal decomposition of MCH [89]. The model was tested against experimental published data over a wide range of temperatures (723–1192 K) and conversion (up to more than 90%), at near atmospheric pressure. The model appeared robust enough to be simulated over a wider range of temperatures (523–1273 K) in order to identify the main consumption and production pathways, in particular the aromatization pathways vs. temperature. Under these conditions, the aromatic compounds are mainly formed by dehydrogenation and dealkylation reactions of cyclohexene and alkylcyclohexenes, whatever the temperature. One key point is the formation of cyclohexene and alkylcyclohexenes. It was shown that, at high temperature, they are exclusively formed by free-radical reactions with decompositions by  $\beta$ -scission of C—C and C—H bonds. At low temperature, molecular Diels-Alder reactions become the main pathway.

The thermal decomposition of MCH follows a radical chain mechanism, which mainly includes the C—C bond scission, H-atom abstraction, secondary reactions, and biradical reactions [90]. Thermodynamic data for selected species involved in this study were computed, and the rate constants for all elementary reactions were evaluated with conventional transition state theory in the temperature range of 298–2000 K, where the Eckart method was adopted to correct the quantum mechanical tunneling effect. The rate constants were in reasonable agreement with experimental measurements and previous theoretical reports. The final products of MCH thermal decomposition are methane, ethene, propene, 1,3-butadiene, isoprene, and 1,3-pentadiene.

Synchrotron vacuum UV photoionization mass spectrometry (PIMS) combined with molecular-beam sampling was used to investigate the species formed during the pyrolysis of methylcyclohexane and in pre-mixed flames of methylcyclohexane [91]. A number of pyrolysis and flame intermediates were identified and quantified, especially including radicals (e.g.,  $\text{CH}_3$ ,  $\text{C}_3\text{H}_3$ ,  $\text{C}_3\text{H}_5$ , and  $\text{C}_5\text{H}_5$ ) and cyclic  $\text{C}_6$ - and  $\text{C}_7$ -intermediates (benzene, 1,3-cyclohexadiene, cyclohexene, toluene,  $\text{C}_7\text{H}_{10}$ , and  $\text{C}_7\text{H}_{12}$ ). The observation of cyclic  $\text{C}_6$ - and  $\text{C}_7$ -intermediates provided important experimental evidence to clarify the special formation channels of toluene and benzene that were observed with high concentrations in both pyrolysis and flame of methylcyclohexane. A kinetic model of methylcyclohexane combustion with 249 species and 1570 reactions was developed including a new sub-mechanism of MCH decomposition.

A combined experimental and chemical kinetic modeling study of the high-temperature ignition and pyrolysis of 1,3-dimethylcyclohexane measured ignition-delay times behind reflected shock waves over a temperature range of 1049–1544 K and pressures of 3.0–12 atm [92]. Pyrolysis was investigated at average pressures of 4 atm at temperatures of 1238, 1302, and 1406 K. By means of mid-infrared direct laser absorption at 3.39  $\mu\text{m}$ , fuel concentration time histories were measured under ignition and pyrolysis conditions. Ignition measurements showed that the ignition-delay times of 1,3-dimethylcyclohexane were longer than those of its isomer, ethylcyclohexane.

The thermal decomposition of MCH was investigated using reactive molecular dynamics and density functional theory calculations in order to better understand the initiation and intermediate reaction mechanisms associated with the high-temperature pyrolysis of methylcyclohexane [93]. It was shown that the pyrolysis of MCH is initiated by four types of reaction channels. The initiation of the decomposition is mainly through the C–C bond homolysis of the six-membered ring, leading to ring opening and the formation of  $\text{C}_7\text{H}_{14}$  diradicals. Subsequently, the biradicals undergo successive decomposition by the  $\beta$ -scission of the C–C bonds to form ethene. The apparent activation energy extracted from the simulations was 263 kJ/mol at temperatures from 2300 to 3100 K, which was reasonably consistent with experimental results.

### 7.3.2 Catalytic Decomposition (Dehydrogenation) of Methylcyclohexane

There are numerous publications about the dehydrogenation of cyclohexane (not included here), and many of those relate to the dehydrogenation of MCH. The rapid dehydrogenation of MCH as an endothermic fuel and as a hydrogen storage medium depends on the availability of active catalysts [94–105], some of which are based on zeolites [106]. Similar catalysts and reactors are applicable to the dehydrogenation of decalin. Catalyst development work for this dehydrogenation reaction may initially have been motivated by the petroleum refining industry in trying to improve the octane rating of gasoline, but most of the recent work was in support of the use of MCH as a reversible hydrogen storage medium. Its use in endothermic fuels for cooling of hypersonic flight vehicles would benefit from all of these previous uses. The effect of propane on the catalytic dehydrogenation of MCH was investigated [97].

Rhodium catalysts supported on  $\text{SiO}_2\text{--Al}_2\text{O}_3$  oxides with varying  $\text{SiO}_2$  content were evaluated in the cracking reaction of methylcyclohexane at 873–1023 K (600–750  $^\circ\text{C}$ ) and 4 MPa [107]. It was found that  $\text{Rh/SiO}_2/\text{Al}_2\text{O}_3$  catalysts exhibited better cracking activity than thermal cracking tested in parallel tests under identical operating conditions. The catalytic activity of these Rh-supported catalysts depended greatly on the  $\text{SiO}_2$  content. The activity initially increased with the content of  $\text{SiO}_2$ , until about 60 mass-%, and then it declined when  $\text{SiO}_2$  constituted a majority (85 and 100 mass-%) in the catalyst carrier. Particularly, catalysts with 60 mass-%  $\text{SiO}_2$  achieved the best catalytic performance with regard to the gas yield, methylcyclohex-

ane conversion, and heat sink capability, which were increased by 56.1%, 16.0%, and 0.28 MJ/kg, respectively, in comparison to thermal cracking at 948 K (675 °C).

Three types of  $\text{ZrO}_2/\text{TiO}_2/\text{Al}_2\text{O}_3$  catalysts with and without platinum active metal were prepared to investigate the coke deposition during pyrolysis of supercritical MCH at 923 K (650 °C) and 4 MPa [108]. Based on GC/MS analysis results, it was observed that the alkene content in liquid products over platinum-loaded catalysts was higher than that in products obtained on bare supports. But for the aromatics, e.g., benzene and toluene, the yields over platinum-loaded samples were obviously less than those on bare supports. It was found that the deposition of platinum on the metal oxide catalyst supports prevented the formation of aromatics. The coke formed over pure supports was more crystalline ordered, with a higher dehydrogenation extent than those produced on the platinum-loaded samples. Platinum-loaded catalysts restrained the generation and polymerization of coke intermediates.

Cracking of MCH in a micro-channel reactor was investigated under supercritical conditions with a series of transition metal M (M = Fe, Co, Ni)-loaded  $\text{SiO}_2$  catalysts coated on the inner wall of stainless-steel tubes in micro-channel reactors [109]. The results showed that the cracking activity and endothermic capacity of MCH increased in the following order:  $\text{Fe}/\text{SiO}_2 < \text{Co}/\text{SiO}_2 < \text{Ni}/\text{SiO}_2$ . The gas yield, conversion, and heat sink capability at 1023 K (750 °C) over  $\text{Ni}/\text{SiO}_2$  increased by 15.4%, 21.3%, and 0.32 MJ/kg, respectively, compared with non-catalyzed thermal cracking.

Monolithic catalysts made from a skeleton of high-thermal-conductivity open-celled metal foam coated with a catalytic coating of zeolites were characterized by Fourier-transform infrared spectroscopy (FTIR) analysis and  $\text{NH}_3$ -temperature programmed desorption analysis [110]. In initial experiments of H-ZSM-5 catalyst pellets, the conversion of MCH was only about 82%. In the case of the H-ZSM-5 catalyst supported on metal foam, the conversion of MCH was about 93%, and the conversion was 11% higher than that of the pelletized zeolite catalyst itself.

### 7.3.3 Oxidation of Methylcyclohexane

Oxidation of MCH leading to ignition and combustion will be discussed in more detail in Volume 5 together with non-hypergolic bipropellant combinations. Here are a few publications that deal both with decomposition and oxidation, and they may be referenced in both places. In many instances, decomposition precedes ignition and combustion.

Although the combustion chemistry of aliphatic hydrocarbons has been extensively documented, the oxidation of cyclic hydrocarbons has been studied to a much lesser extent. To provide a better understanding of the combustion chemistry of cycloaliphatics, the oxidation of MCH was studied in a series of high-temperature shock tube experiments [111]. Ignition-delay times for a series of mixtures of varying MCH/oxygen equivalence ratios ( $\varphi = 0.5, 1.0, 2.0$ ) were measured over reflected shock

temperatures of 1200–2100 K and reflected shock pressures of 1.0, 2.0, and 4.0 atm. A detailed chemical kinetic mechanism was assembled to simulate the shock tube results and flow reactor experiments, with good agreement observed.

#### 7.4 Safety Properties of Methylcyclohexane

Based on information in material safety data sheets (MSDSs), the flammability range of methylcyclohexane in air is 1.2 to 6.7 vol.-%. The closed-cup flash point is 269 K ( $-3.9^{\circ}\text{C} = 25^{\circ}\text{F}$ ). The autoignition temperature of methylcyclohexane in air is 538 K ( $265^{\circ}\text{C} = 509^{\circ}\text{F}$ ).

#### 7.5 Toxicity of Methylcyclohexane

Four animal species were exposed for 1 year to selected vapor concentrations of MCH to determine its long-term toxic effects [112, 113]. Year-long exposures of animals were conducted to MCH at 0, 400, and 2000 parts per million (ppm). Rats, mice, and hamsters were held for 1 year post exposure, while dogs were held for 5 years post exposure. Mean body weight depression was observed in the MCH-exposed hamsters and male rats. The only significant lesion noted in any of the animals was progressive renal nephropathy, which was seen in virtually all of the male rats. The acute toxicity of MCH is as follows: oral mouse LD<sub>50</sub>, 2250 mg/kg; inhalation mouse LC<sub>50</sub>, 41500 mg/m<sup>3</sup> for two hours.

The American Conference of Governmental Industrial Hygienists (ACGIH) recommended threshold limit value (TLV) for methylcyclohexane is 400 ppm (time-weighted average [TWA]). The U.S. Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) TWA is 500 ppm (2000 mg/m<sup>3</sup>), and the National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL) TWA is 400 ppm (1600 mg/m<sup>3</sup>). The NIOSH Immediately Dangerous to Life and Health (IDLH) limit is 1200 ppm, which is also the lower limit of flammability in air [114, 115].

#### 7.6 Applications of Methylcyclohexane

Methylcyclohexane is used as a fuel constituent in JP-9. The air-launched cruise missile uses PF-1 priming fluid (MIL-P-87173) to aid in engine ignition. PF-1 is approximately 90% JP-10 and 10% MCH. Physical properties have been estimated for binary mixtures of MCH and low molecular weight hydrocarbons for mixtures containing ethane, propane, and *n*-butane [97].

## 8 Ethylcyclohexane and Diethylcyclohexane

Rocketdyne conducted extensive experimentation with diethylcyclohexane (DECH) in 1959 and proposed it as an alternative to RP-1 because of its reduced coking, lower sulfur content, higher heat transfer coefficient, and lower freezing point. Of the relatively few candidate chemicals that had sufficiently wide commercial availability and physical properties similar to RP-1 to enable direct substitution, DECH and *p*-menthane were selected for detailed experimental evaluation [116]. DECH is a highly reproducible mixture of isomers readily available from the polymer industry. Even though the experiments succeeded in showing DECH as being appreciably superior to RP-1, it was too late for a changeover. The development of the Atlas and Titan-I intercontinental ballistic missile (ICBM) systems had proceeded too far to justify changing from RP-1 fuel to DECH, and RP-1's incumbency as the standard U.S. hydrocarbon rocket fuel has continued from then to the present day [117] (or until it was replaced by RP-2). It now appears that current batches of RP-1 and its more advanced versions do contain large quantities of the branched cyclohexanes, but at a cost of only 20% of that of the projected cost of DECH.

The pyrolysis of ethylcyclohexane (ECH) was studied in a flow reactor at atmospheric pressure [118]. The pyrolysis products were analyzed by synchrotron vacuum UV PIMS and gas chromatography. Dozens of species were identified and quantified, including many isomers, in order to investigate the primary decomposition of ECH, including its initial decomposition, isomerization, and further reactions of the cyclic  $C_8H_{15}$  radicals formed from the H-abstraction of ECH. The observation of  $C_8H_{16}$  alkene indicated the existence of ring-opening isomerization reaction of ECH. The ring-opening isomerization reaction of cyclic  $C_8H_{15}$  radicals produces alkenyl radicals, whose further decomposition constitutes the various chain and branched intermediates in ECH pyrolysis. The formation of isoprene and vinylcyclopentane is due to isomerization reactions of radical addition on the double bond of alkenyl radicals.

Ethylcyclohexane is a model compound for cycloalkanes with long alkyl side chains [119]. The flow reactor pyrolysis of ECH at various pressures (30, 150, and 760 mm Hg) was studied using synchrotron vacuum UV PIMS and gas chromatography. The mole-fraction profiles of numerous major and minor species were evaluated, and good agreement was observed between the PIMS and GC data sets. A detailed kinetic model for ECH high-temperature pyrolysis and oxidation was developed and validated against the pyrolysis and flame data. Further validation of the kinetic model was presented by comparison with literature data, including species concentrations in jet-stirred reactor oxidation, ignition-delay times in a shock tube, and laminar flame speeds at various pressures and equivalence ratios. The model predicted the rate of consumption of ECH, the growth of aromatics, and the global combustion properties. Reaction flux and sensitivity analysis were used to explain chemical kinetic features of ECH combustion under various reaction conditions.

The standard enthalpy of formation of a similar homologue molecule, dimethylcyclohexane vapor, is  $-181 \text{ kJ/mol}$  ( $-43.26 \text{ kcal/mol}$ ) [120].

## 9 Propylcyclohexane

Propylcyclohexane,  $\text{C}_9\text{H}_{18}$ , CAS RN [1678-92-8], has not been used as a rocket fuel as such, but the physical and thermochemical properties of pure propylcyclohexane were measured so that it could be used as a constituent of surrogate fuel mixtures. This was done as part of an effort to develop surrogate fuels to represent the thermophysical properties of aviation kerosenes with the more general description of Jet-A and JP-8 [71]. It was not always clear whether the compounds tested were *n*-propylcyclohexane or isopropylcyclohexane. One must assume that the properties of these two structural isomers differ slightly.

### 9.1 Physical Properties of Propylcyclohexane

Data for density, velocity of sound, and adiabatic compressibility of propylcyclohexane are listed in Table 11 in the section on methylcyclohexane. The thermal conductivity of propylcyclohexane liquid and vapor was measured in comparison to that of methylcyclohexane, covering a temperature range of 300 to 600 K and a pressure range of 0.1 to 60 MPa and was used to develop a correlation for the thermal conductivity [69]. The thermal conductivity of liquid propylcyclohexane at 300 K is  $0.111 \text{ W m}^{-1} \text{ K}^{-1}$  at a density of  $788 \text{ kg/m}^3$ . The thermal conductivity of liquid propylcyclohexane at 450 K under 50 MPa pressure is  $0.105 \text{ W m}^{-1} \text{ K}^{-1}$  at a density of  $729 \text{ kg/m}^3$ .

### 9.2 Chemical Properties of Propylcyclohexane

Aliquots of propylcyclohexane were thermally stressed in sealed stainless-steel ampule reactors with an initial pressure of 34.5 MPa (5000 psi) and temperatures of 648, 673, 698, and 723 K (375, 400, 425, and 450 °C) [121]. These conditions represented the high-pressure conditions that existed during some of physical property measurements. This temperature range was chosen because it allowed for reaction times of a convenient length. At 648 K (375 °C), the reaction was relatively slow, so reaction times ranged from 16 to 32 h. At 723 K (450 °C), the reaction was much faster, so reaction times ranged from 10 to 40 min. At each temperature, the extent of decomposition was determined as a function of time by gas chromatography. These data were used to derive first-order rate constants for the decomposition of propylcyclohexane. Decomposition rate constants ranged from  $3.66 \times 10^{-7} \text{ s}^{-1}$  at 648 K (375 °C) to  $8.63 \times 10^{-5} \text{ s}^{-1}$  at

723 K (450 °C). The kinetic data were used to determine Arrhenius parameters of  $A = 2.56 \times 10^{16} \text{ s}^{-1}$  and  $E_{\text{act}} = 283 \text{ kJ/mol}$ .

In a similar test, the thermal decomposition kinetics of 1,3,5-triisopropylcyclohexane were studied between 623 and 698 K (350 and 425 °C) in stainless-steel ampule reactors [122]. At each temperature, the extent of decomposition as a function of time was determined by analyzing the thermally stressed liquid phase by gas chromatography. These data were used to derive pseudo-first-order rate constants that ranged from  $2.38 \times 10^{-7} \text{ s}^{-1}$  at 623 K (350 °C) to  $7.28 \times 10^{-5} \text{ s}^{-1}$  at 698 K (425 °C). The Arrhenius parameters of the thermal decomposition of 1,3,5-triisopropylcyclohexane were  $A = 5.67 \times 10^{16} \text{ s}^{-1}$  and  $E_{\text{act}} = 279 \text{ kJ/mol}$ . The kinetics of *n*-alkylcyclohexane pyrolysis depend on the chain length of the attached alkyl group [123].

### 9.3 Fused-Ring Cycloaliphatic Compounds

Attaching one or several cycloaliphatic rings to each other or making bridging bonds across the inside of a ring from two opposite carbon atoms opens up a new field of high-energy fuels that are used mostly for air-breathing engines but may have potential use as high-density rocket fuels. Illustrating the chemical structures of many of these molecules requires 3D drawings, which are hard to reproduce here in 2 dimensions on flat paper. It would be desirable to display these 3D molecular structures in this book as GIF images that would rotate in front of the viewer and allow observation of the molecules from all angles of view. Some websites already have that capability.

## 10 Tetralin

Tetralin, also known as 1,2,3,4-tetrahydronaphthalene, tetrahydronaphthalene,  $\text{C}_{10}\text{H}_{12}$ , CAS RN [119-64-2], is an aromatic hydrocarbon and should be discussed in the chapter “Aromatic Hydrocarbons.” Because it is so closely related to decalin, it is discussed here next to decalin, the result of complete hydrogenation of naphthalene.

### 10.1 Physical Properties of Tetralin

Tetralin freezes at 237.3 K (−35.8 °C) and boils at 481 K (207.6 °C). The density of tetralin at 293 K is  $0.9702 \text{ g/cm}^3$  [124]. The vapor pressure of liquid tetralin in the temperature range 370–446 K can be calculated from the equation

$$\log P = (-2797.9/T) + 11.954 - 1.187 \log T$$

where  $P$  is the vapor pressure in mmHg and  $T$  is the temperature in kelvin [2]. The enthalpy of formation of tetralin vapor is  $+22.1 \pm 3.4$  kJ/mol ( $+5.29 \pm 0.81$  kcal/mol). The enthalpy of formation of liquid tetralin is  $-33.1 \pm 2.1$  kJ/mol ( $-7.91 \pm 0.51$  kcal/mol). The heat of combustion of liquid tetralin is  $5617 \pm 2$  kJ/mol ( $1342.6 \pm 0.51$  kcal/mol). The heat of evaporation of liquid tetralin is  $55.2 \pm 1.2$  kJ/mol ( $13.20 \pm 0.3$  kcal/mol) at 298 K and  $49.9 \pm 0.8$  kJ/mol ( $11.92 \pm 0.2$  kcal/mol) at 380 K. The refractive index  $n_D^{20}$  of tetralin is 1.5413.

The results of heat capacity measurements of subcritical tetralin at saturation pressure between 300 and 720 K were given only in table format [125]. It would have been more practical to give the parameters for a curve-fitted polynomial equation.

## 10.2 Safety Properties of Tetralin

### 10.2.1 Flammability of Tetralin

The autoignition temperature of tetralin in air is 696 K ( $423^\circ\text{C} = 794^\circ\text{F}$ ), which is much higher than that of decalin.

### 10.3 Toxicity of Tetralin

The LD50 (rats, oral) of tetralin is 2.68 g/kg. Tetralin induces methemoglobinemia.

## 11 Decalin

Decalin, also known as decahydronaphthalene, bicyclo[4.4.0]decane,  $\text{C}_{10}\text{H}_{18}$ , *cis*-decalin [CAS RN 493-01-6], *trans*-decalin [CAS RN 493-02-7], also CAS RN [91-17-8], has been used as an endothermic fuel and as a fuel additive. Decalin is thermally stable and readily available and has advantages in high-speed vehicle applications because of its relatively low vapor pressure, high density, and good volumetric heat of combustion.

### 11.1 Preparation of Decalin

Decalin is prepared by hydrogenation of naphthalene in the presence of a catalyst. A commercial mixture of *trans/cis*-decahydronaphthalene produced by DuPont may be sold as a brand-marked chemical and is spelled with a capital first letter: Decalin.

Decahydronaphthalene (decalin) is a potential fuel that could provide the heat sink required for high-Mach air-breathing vehicles. At the beginning of these programs, domestic suppliers of decalin were identified, and production rates were deter-

mined. Only one producer of decalin was identified, but production capacity of these cycloalkane materials was limited at that time, and the materials were sold only as specialty chemicals with an associated high cost.

## 11.2 Physical Properties of Decalin

Physical properties of decalin are listed in Table 16. A separate table, Table 19, gives the thermodynamic properties of decalin.

**Table 16:** Physical properties of decalin.

| Property                                                      | SI units                                               | Other units                                              | References |
|---------------------------------------------------------------|--------------------------------------------------------|----------------------------------------------------------|------------|
| Molecular mass                                                | 138.2499 g/mol                                         | 7.2333 mol/kg                                            |            |

| Critical pressure, <i>cis</i> -decalin                        | 32 ± 2 bar                                             | 31.6 ± 2 atm                                             |            |

### 11.2.1 Freezing Point of Decalin

The freezing points of the two conformers of decalin are quite different: *trans*-decalin melts at 242.7 K (−30.4 °C = −22.7 °F) and *cis*-decalin melts at 230.3 K (−42.9 °C = −45.2 °F). The fusion temperature listed in NIST Chemistry WebBook (149 K) is in error.

### 11.2.2 Boiling Point of Decalin

The boiling points of the two conformers of decalin are quite different: *trans*-decalin boils at 460 K (187 °C = 369 °F), and *cis*-decalin boils at 469 K (196 °C = 384 °F).

### 11.2.3 Vapor Pressure of Decalin

The NIST Chemistry WebBook website gives Antoine equations for decalin for the range 373–469 K, both for *cis*- and *trans*-decalin. The first equation is for *cis*-decalin:

$$\log P = A - [B/(T + C)] = 4.00047 - [1594.687/(T - 69.731)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. And the same type of equation for the vapor pressure of *trans*-decalin is

$$\log P = A - [B/(T + C)] = 3.99304 - [1572.899/(T - 65.947)]$$

Vapor-pressure data derived from these equations are shown in Figure 8 to illustrate the difference between the two conformers.

**Figure 8:** Vapor pressures of *cis*- and *trans*-decalin. (Image created by Schmidt 2020 based on data from [17].)

### 11.2.4 Density of Decalin

A study of the stereoisomeric influence and effect on the density of decalin was performed by carrying out experimental measurements up to 100 MPa in the temperature range 293–353 K in increments of 10 K [130]. The density of *cis*- and *trans*-decalin as a function of temperature is shown in Figure 9. The density of *cis*-decalin is substantially higher than that of *trans*-decalin. Similar data were reported 60 years earlier [128]. A similar relationship was observed for viscosity.

**Figure 9:** Density of *cis*- (—) and *trans*- (---) decalin as a function of temperature. (Image created by Schmidt 2020 based on data from [130].)

**Figure 10:** Density of *cis*- (—) and *trans*- (---) decalin as a function of pressure. (Image created by Schmidt 2020 based on data from [130].)

The density of *cis*- and *trans*-decalin at 293 K as a function of pressure is shown in Figure 10. Data for density and dynamic viscosity of a decalin isomer mixture (41.06% *cis* and 58.69% *trans*), a commercial grade of decalin, are listed in Table 17. That reference also contains data on mixtures of decalin with cyclohexane or toluene. Single-point measurements for densities of *cis*- and *trans*-decalin gave *cis*-decalin  $\rho = 0.89685 \text{ g/cm}^3$  and *trans*-decalin  $\rho = 0.86978 \text{ g/cm}^3$  [131].

**Table 17:** Density and dynamic viscosity of a decalin isomer mixture (41.06% *cis* and 58.69% *trans*).

| Temperature<br><i>T</i> | Density<br>kg/m <sup>3</sup> | Viscosity<br>mPa s |
|-------------------------|------------------------------|--------------------|
| 283                     | 0.88780                      | 3.09742            |
| 293                     | 0.88025                      | 2.50378            |
| 303                     | 0.87270                      | 2.06586            |
| 313                     | 0.86515                      | 1.73385            |
| 323                     | 0.85765                      | 1.47722            |

Data source: [132]

### 11.2.5 Viscosity of Decalin

The viscosity of the *cis* and *trans* isomers of decalin has been measured in the range 243 to 453 K (−30 to +180 °C) [127]. The viscosity of the *trans* isomer was always less than that of the *cis* isomer. Viscosity measurements have been made on nine pure hydrocarbon liquids, including *cis*- and *trans*-decalin, at six temperatures ranging from 288 to 408 K (15 to 135 °C) and at pressures as high as 4000 bars [133].

A study of the stereoisomeric influence and effect on the dynamic viscosity was performed by carrying out experimental measurements up to 100 MPa in the temperature range 293 to 353 K in increments of 10 K [130]. Decahydronaphthalene (decalin) exists in two stereoisomeric molecular configurations, a *cis* and a *trans* configuration. The *cis* and *trans* isomers have different physical properties. In a study of the stereoisomeric effect on the dynamic viscosity (and density) versus pressure and temperature at up to 100 MPa in the temperature range 293 to 353 K, it was found that the viscosity of *cis*-decalin is higher than that of *trans*-decalin in the considered temperature and pressure ranges due to the twisted structure of *cis*-decalin compared to the relatively more symmetrical and rigid structure of *trans*-decalin (Figures 11 and 12). The density of *cis*-decalin is around 3% higher than for *trans*-decalin.

The dynamic viscosity of decalin at atmospheric pressure as a function of temperature is illustrated in Figure 12. The viscosity of liquid *cis*-decalin is higher than that of *trans*-decalin. The higher viscosity of liquid *cis*-decalin is due to its more twisted and less symmetrical molecular structure compared to the relatively more symmetrical and rigid molecule of *trans*-decalin.

Data for dynamic viscosity of a decalin isomer mixture (41.06% *cis* and 58.69% *trans*) are included in Table 17 (in the density section) [132]. That reference also includes viscosity data for mixtures of decalin with cyclohexane or toluene.

Viscosity and density measurements for binary mixtures composed of methylcyclohexane and *cis*-decalin in the temperature range 293 to 353 K and at pressures up to 100 MPa were carried out with a falling-body viscometer, except at atmospheric pressure, where an Ubbelohde viscometer was used [134]. The density was measured up to 60 MPa and was extrapolated by a Tait-type relationship to 100 MPa.

**Figure 11:** Viscosity as a function of pressure for *cis*-decalin (—) and *trans*-decalin (---). (Image created by Schmidt 2020 based on data from [130].)

**Figure 12:** Dynamic viscosity as a function of temperature for *cis*-decalin and *trans*-decalin. (Image created by Schmidt 2020 based on data from [130].)

The dynamic viscosities of controlled mixtures of *cis*- and *trans*-decalin were measured as a function of the *cis* : *trans* ratio for five different mixtures at three temperatures K and six isobars up to 100 MPa, as shown in Figure 13 [135, 136]. The variations of dynamic viscosity versus composition were discussed with respect to their behavior due to stereoisomerism. Four different models with a physical and theoretical background were studied in order to investigate how they take the stereoisomeric effect into account through their required model parameters. All the models were able to distinguish between the two stereoisomeric decalin compounds.

**Figure 13:** Dynamic viscosity versus mol fraction  $x$  for *cis*-decalin. (Image created by Schmidt 2020 based on data from [135].)

Legend: At 20 MPa (bottom three lines, thin lines —) and 100 MPa (top three lines, heavy lines —) for various isotherms (open triangle = 303 K,  $\times$  = 323 K, and open circles = 343 K).

The viscosities, flash points, and refractive indices of mixtures of decalin with  $C_9$  to  $C_{11}$  *n*-alkanes were measured at pressure  $p = 0.1$  MPa and different temperatures ranging from 293 to 323 K [131]. In addition to data for hydrocarbon mixtures, that study included viscosity data for the pure compounds, with the results shown in Table 18.

The transport properties of mixtures of decalin with propane were modeled. Propane was added to decalin as a supercritical fluid solvent that was supposed to help transfer heat from the wall to the suspended decalin molecules for dehydrogenation and release of dihydrogen. The density and viscosity of propane mixed with 66/34 *trans/cis*-decahydronaphthalene were measured over a wide range of

**Table 18:** Dynamic viscosity of *cis*- and *trans*-decalin

| Temperature, K | Dynamic viscosity, mPa s |                       |
|----------------|--------------------------|-----------------------|
|                | <i>cis</i> -decalin      | <i>trans</i> -decalin |
| 293.15         | 3.355                    | 2.112                 |
| 298.15         | 3.011                    | 1.925                 |
| 303.15         | 2.718                    | 1.769                 |
| 308.15         | 2.470                    | 1.628                 |
| 313.15         | 2.252                    | 1.505                 |
| 318.15         | 2.079                    | 1.394                 |
| 323.15         | 1.912                    | 1.295                 |

Data source: [131]

temperatures (323–423 K), pressures (2.5–208 bar), and compositions (0–65 mol-% propane) [137].

### 11.2.6 Surface Tension of Decalin

The surface tension of *cis*- and *trans*-decalin was measured over the temperature range 253 to 453 K (–30 to +180 °C) along with the density of the same samples [128]. The surface tensions of *cis*- and *trans*-decalin at 293 K (20 °C) were 32.18 and 29.89 mN/m (32.18 and 29.89 dyn/cm) for samples with densities of 0.8967 and 0.8700 g/cm<sup>3</sup>, respectively.

### 11.2.7 Thermal Conductivity of Decalin

The thermal conductivity  $\lambda$  was measured in the temperature range 302–392 K for the *cis* and *trans* isomers of decahydronaphthalene and their commercially available mixture (32.15 mass-% *trans*) [129]. See also [138].

### 11.2.8 Thermodynamic Properties of Decalin

Thermodynamic properties of decalin are summarized in Table 19.

**Table 19:** Thermodynamic properties of decalin.

| Property                                                                          | SI units                                          | Other units                                              |
|-----------------------------------------------------------------------------------|---------------------------------------------------|----------------------------------------------------------|
| Molecular mass                                                                    | 138.2499 g/mol                                    | 7.2333 mol/kg                                            |
| Heat capacity, $C_p$ , vapor, at 298 K, <i>cis</i> -decalin                       | $168.1 \pm 1.0 \text{ J mol}^{-1} \text{ K}^{-1}$ | $40.18 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$ |
| Heat capacity, $C_p$ , vapor, at 298 K, <i>trans</i> -decalin                     | $168.6 \pm 1.0 \text{ J mol}^{-1} \text{ K}^{-1}$ | $40.30 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$ |
| Heat capacity, $C_p$ , liquid, at 298 K                                           | $232.08 \text{ J mol}^{-1} \text{ K}^{-1}$        | $55.46 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$ |
| Heat capacity, $C_p$ , liquid, at 298 K, <i>trans</i> -decalin                    | $229.17 \text{ J mol}^{-1} \text{ K}^{-1}$        | $54.77 \text{ cal mol}^{-1} \text{ }^\circ\text{C}^{-1}$ |
| Standard enthalpy of formation, vapor, $\Delta H_f^{298}$ , <i>cis</i> -decalin   | $-169.2 \pm 2.3 \text{ kJ/mol}$                   | $-40.44 \pm 0.55 \text{ kcal/mol}$                       |
| Standard enthalpy of formation, vapor, $\Delta H_f^{298}$ , <i>trans</i> -decalin | $-182.2 \pm 2.3 \text{ kJ/mol}$                   | $-43.55 \pm 0.55 \text{ kcal/mol}$                       |
| Heat of combustion, liquid, <i>cis</i> -decalin                                   | $6288.22 \pm 0.92 \text{ kJ/mol}$                 | $1502.8 \pm 0.22 \text{ kcal/mol}$                       |
| Heat of combustion, liquid, <i>trans</i> -decalin                                 | $6276.96 \pm 0.92 \text{ kJ/mol}$                 | $1500.2 \pm 0.22 \text{ kcal/mol}$                       |
| Enthalpy of formation, liquid, $\Delta H_f^{298}$ , <i>cis</i> -decalin           | $-281.05 \text{ kJ/mol}$                          | $-67.17 \text{ kcal/mol}$                                |
| Enthalpy of formation, liquid, $\Delta H_f^{298}$ , <i>trans</i> -decalin         | $-230.7 \pm 0.92 \text{ kJ/mol}$                  | $-55.14 \pm 0.22 \text{ kcal/mol}$                       |
| Enthalpy of vaporization at NBP, <i>cis</i> -decalin                              | $50.2 \pm 2.1 \text{ kJ/mol}$                     | $12.00 \pm 0.50 \text{ kcal/mol}$                        |
| Enthalpy of vaporization at NBP, <i>trans</i> -decalin                            | $48.5 \pm 2.1 \text{ kJ/mol}$                     | $11.59 \pm 0.50 \text{ kcal/mol}$                        |

NBP = normal boiling point; Data source: [17]

### 11.2.8.1 Heat Capacity of Decalin

The heat capacity of a commercial mixture of decalin stereoisomers as a function of temperature is illustrated in Figure 14.

**Figure 14:** Heat capacity of a commercial mixture of liquid decalin stereoisomers as a function of temperature. (Reproduced and modified from [126].)

### 11.2.8.2 Enthalpy of Formation of Decalin

The stereoisomers of decalin have slightly different enthalpies of formation:  $\Delta H_f^{298}$ , *cis*-decalin =  $-281.05 \text{ kJ/mol} = -67.17 \text{ kcal/mol}$  and  $\Delta H_f^{298}$  and *trans*-decalin =  $-230.7 \pm 0.92 \text{ kJ/mol} = -55.14 \pm 0.22 \text{ kcal/mol}$ .

### 11.2.8.3 Enthalpy of Vaporization and Enthalpy of Sublimation of Decalin

The heat of sublimation of *cis*-decahydronaphthalene is  $64.8 \text{ kJ/mol}$  at  $230 \text{ K}$  and  $62.5 \text{ kJ/mol}$  at  $298 \text{ K}$ . The heat of sublimation of *trans*-decahydronaphthalene is  $66.2 \text{ kJ/mol}$  at  $241 \text{ K}$  and  $64.3 \text{ kJ/mol}$  at  $298 \text{ K}$  [139]. The enthalpy of vaporization of a stereoisomer mixture of decalins as a function of temperature at the saturation point is illustrated in Figure 15.

**Figure 15:** Enthalpy of vaporization of a stereoisomer mixture of decalins as a function of temperature at the saturation point. (Reproduced and modified from [126].)

## 11.2.9 Optical Properties of Decalin

### 11.2.9.1 Infrared Spectrum of Decalin

The IR spectrum of *cis*-decalin is shown in Figure 16.

**Figure 16:** Infrared spectrum of *cis*-decahydronaphthalene. (Reproduced and modified with permission from [140].)

### 11.2.9.2 Refractive Index of Decalin

Extended measurements of refractive indices of both stereoisomers of decalin over a range of temperatures from 298 to 318 K gave the data listed in Table 20. These data are useful for checking the purity of decalin.

**Table 20:** Refractive indices of *cis*- and *trans*-decalin.

| Temperature, K | Refractive indices, $n_D$ |                       |
|----------------|---------------------------|-----------------------|
|                | <i>cis</i> -decalin       | <i>trans</i> -decalin |
| 293            | 1.4806                    | 1.4691                |
| 298.15         | 1.4776                    | 1.4662                |
| 308.15         | 1.4736                    | 1.4618                |
| 318.15         | 1.4696                    | 1.4581                |

Data source: [131]

### 11.2.10 Molecular Structure of Decalin

Decalin occurs in *cis* and *trans* forms. The *trans* form is energetically more stable because of fewer steric interactions. *Cis*-decalin is a chiral molecule without a chiral center; it has a two-fold rotational symmetry axis but no reflective symmetry. However, the chirality is canceled through a chair-flipping isomerization process that turns the molecule into its mirror image. *Trans*-decalin is relatively symmetrical and rigid compared to *cis*-decalin, which is a twisted and less symmetrical molecule but more flexible, as it can flip from one configuration to another. Although *cis* and *trans* molecules have the same molecular constitution, they have different physical properties because of their different molecular configurations.

### 11.3 Chemical Properties of Decalin

Technical-grade decalin may contain several percent of tetralin as contaminant, a result of incomplete hydrogenation when decalin is made by reducing naphthalene.

#### 11.3.1 Thermal Decomposition of Decalin

The vapor-phase thermal decomposition of *trans*-decalin and naphthalene has been measured under precisely controlled conditions of reaction atmosphere, exposure temperature, and residence time at atmospheric pressure and at temperatures from 300 to 1050 K [78]. Differences in fuel thermal decomposition were analyzed with respect to molecular structure and thermochemical bond energy analysis. The thermal decomposition data for these compounds were used to evaluate their potential heat-sink capacities. In a separate but related study, the gas-phase thermal degradation behavior of decalin was examined for a broad range of reaction conditions. The results indicated that removal of oxygen from the fuel-handling system and a reduction in high-temperature exposure time will greatly enhance the fuel's gas-phase stability. Under pyrolytic reaction conditions, the nature of *trans*-decalin reaction products was consistent with an initial degradation pathway involving bond homolysis followed by H-atom abstraction reactions.

Studies on the effect of low oxygen concentrations on the thermal stability of decalin indicated that stringent control of the oxygen content of fuels in the sub-parts-per-million region markedly improved thermal stability, and hence decreased heat exchanger fouling. A test program was conducted to determine the thermal stability and thermal cracking properties of decalin. Compared to JP-7, decalin was more stable to thermal decomposition.

The pyrolysis of decalin as an endothermic fuel was measured in a flow reactor using synchrotron vacuum ultraviolet photoionization mass spectrometry (SVUV-PIMS) at 4, 20, and 101 kPa and 920–1500 K [141]. Dozens of pyrolysis species, particularly several free radicals and aromatic species, were identified, and their mole fraction profiles were measured as a function of temperature. A detailed kinetic model consisting of 484 species and 1774 reactions was developed and used to simulate the experimental data. A rate of production analysis and sensitivity analysis was performed in order to provide insight into the pyrolysis kinetics of decalin. The decomposition of decalin is initiated by C—C bond dissociation reactions of both decalin and its C<sub>10</sub>H<sub>18</sub> isomers, while the H-atom abstraction reactions consume most of decalin. Monocyclic aromatic hydrocarbons (MAHs) are mainly produced in the fuel decomposition process instead of the mass growth process from small molecules, indicating that the two fused six-membered ring structure offers a solid infrastructure to form MAHs. Polycyclic aromatic hydrocarbons (PAHs) are mainly produced in the mass growth pro-

cess from PAH precursors such as benzyl radical ( $\phi\text{CH}_2^\bullet$ ), phenyl radical ( $\phi^\bullet$ ), and 1,3-cyclopentadienyl radical. The high degree of saturation of decalin facilitates ring-opening pathways in its decomposition. This enhances the formation of MAHs but limits the formation of PAHs, leading to the lower sooting tendency of decalin compared with tetralin.

### 11.3.2 Catalytic Decomposition of Decalin

The catalyzed decomposition of decalin as an endothermic fuel has been thoroughly investigated [97, 98]. Several publications on this topic have are discussed in the section on endothermic fuels; see chapter “Kerosenes.”

Laboratory studies of the dehydrogenation of decalin to naphthalene over a  $\text{Pt}/\text{Al}_2\text{O}_3$  catalyst have indicated that the reaction proceeds in two stages (with tetralin as the intermediate). Hyperbranched polymer-encapsulated metal nanoparticles (HEMNs) with  $(\text{Pd}, \text{Pt}, \text{Au})@\text{CPAMAM}$  were tested as integrated catalysts for the supercritical cracking of decalin [142]. The metal precursor was extracted into the organic phase using a hydrocarbon-soluble hyperbranched poly(amidoamine) (CPAMAM) and then reduced *in situ* by  $\text{NaBH}_4$  to produce HEMNs with virtually a single-size distribution. The new encapsulation method allowed metal nanoparticles to have a smaller particle size beneficial to their overall specific surface area and a higher proportion of active surface atoms for better catalytic activity. The three HEMNs were highly dispersed in decalin and exhibited good stability under storage tests for up to 12 months and high-temperature stability tests at 453 K (180 °C). During the supercritical cracking of decalin,  $\text{Pd}@\text{CPAMAM}$  had much better catalytic performance than  $\text{Pd}@18\text{N}$  and plain CPAMAM. To obtain the same heat-sink capability of 3.02 MJ/kg, the temperature could be lowered from 998 K (725 °C) (thermal cracking) to 974, 966, and 972 K (701, 693, and 699 °C) for palladium, platinum, and gold HEMNs, respectively. Platinum HEMN turned out to be the best catalyst because of its excellent catalytic dehydrogenation/cracking performance, with the conversion of decalin increasing from 22.3 to 50.7% and the heat-sink capability rising from 2.18 to 2.62 MJ/kg with the addition of only 50 ppm  $\text{Pt}@\text{CPAMAM}$  to decalin, operating at 923 K (675 °C).

### 11.4 Safety Properties of Decalin

Decalin forms explosive organic peroxides upon extended storage in the presence of air. Therefore, it should be stored under nitrogen.

The flammable range of decalin vapors in air is from 0.7 vol.-% to 4.9 vol.-%. The autoignition temperature of decalin in air is 545 K (272 °C = 521 °F), which is much lower

than that of tetralin. Other sources (MSDSs) gave an autoignition temperature of 523 K ( $250^{\circ}\text{C} = 482^{\circ}\text{F}$ ). The autoignition temperature of undecomposed endothermic fuels is an important safety criterion. The flash point of commercial decalin is at 330 K ( $57^{\circ}\text{C} = 135^{\circ}\text{F}$ ). The flash point of *cis*-decalin is 332.6 K, and the flash point of *trans*-decalin is 326.8 K [131].

### 11.5 Toxicity of Decalin

The toxicity of decalin is as follows: oral rat LD<sub>50</sub>, 4170 mg/kg; skin rabbit LD<sub>50</sub>, 5900 mg/kg; inhalation rat LC<sub>50</sub>, 710 ppm/4 h. Decalin has been investigated as a tumorigen.

## 12 Alkyldecalins

Isomerized mixed methyl decalin (MMD-I) is an attractive fuel for ramjets and turbojets. *Exo*-tetrahydrodicyclopentadiene (*exo*-THDC) and isomerized RJ-4 (RJ-4-I) would be excellent fuels for ramjets and liquid propellant guns, but along the same line, MMD-I would also be an attractive fuel for ramjets and turbojets, and *exo*-THDC/60 mass-% RJ-5 and *exo*-THDC/60 mass-% *exo*-tetrahydrotricyclopentadiene mixtures could be used for ramjets.

Branched alkyldecalins are promising jet fuel components with high density, high thermal stability, and low freezing point, but availability is limited by fossil resources. A catalytic one-pot synthesis process using cyclic alcohols (cyclohexanol, cyclopentanol) and branched cycloalkanes (methylcyclohexane, methylcyclopentane) that can be derived from lignocellulose and/or refineries as feedstock is based on consecutive dehydration, alkylation, rearrangement, and hydrogen transfer to produce branched decalins [143]. The dehydration/oligomerization of alcohols also produces branched cycloalkanes, but the carbon yield and selectivity are very low, and the presence of branched cycloalkanes significantly improves the reaction. The reaction goes smoothly at room temperature, and continuous feeding of alcohols can further increase the yield. Under optimized reaction conditions, the carbon yield and branched decalins selectivity vary in the range of 61–87%, depending on the reactants used. The branched decalins have good fuel properties, such as density as high as 0.88 g/mL and freezing point as low as 163 K ( $-110^{\circ}\text{C}$ ), and they can be produced on a large scale.

### 13 Other Fused-Ring Alicyclic Hydrocarbon Fuels

Methylstyrene can be dimerized to 1,1,3-trimethyl-3-phenylindane and can then be hydrogenated to 1,1,3-trimethyl-3-cyclohexyl-hydrindane, which has been patented as a rocket fuel [144].

### 14 Bridged-Ring Alicyclic Polycyclic Hydrocarbons

Bridges connecting opposite atoms in a ring can contain one, two, or several carbon atoms. The bridges are then called methylene, ethylene, or *n*-alkene bridges. Methylene bridges are the ones that will generally increase strain in the molecules and increase their energy content, more so than bridges with two or more carbon-atom members. Bridge formation usually adds to the energy of the molecule and favorably influences physical properties such as low freezing points and low viscosity.

Hydrocarbon fuels with strained molecular conformations or more densely packed molecular structures have high energy content but often exhibit low reactivity, and their ability to improve the performance of practical combustion systems relies strongly on their interaction with the dynamics of the surrounding fluid flow [145]. The intensity of the combustion processes of these materials is dictated, in general, by evaporation, pyrolysis, mixing, and exothermic reactions processes. Unlike other conventional hydrocarbon fuels, the time scales of all these processes are often comparable with each other. It is difficult to devise simpler theoretical models to predict combustion characteristics.

Some fuels that are composed of compact hydrocarbon molecules have energy contents or heating values significantly greater than that of currently used standard missile fuel JP-10 (up to 160000 BTU/gal [44.7 GJ/m<sup>3</sup>] vs. 141700 BTU/gal [39.6 GJ/m<sup>3</sup>] for JP-10) [146].

High-density hydrocarbon fuels consist of naphthenic hydrocarbons, caged hydrocarbons, and fuels with nanoparticles [147]. Through a combination of polymerization, hydrogenation, and isomerization, high-energy fuels with high density, high combustion value, and good quality can be synthesized to satisfy the requirements of hypersonic aircraft and missiles. The high-strain caged hydrocarbons and high-density fuels with nanoparticle additives are promising candidate fuels because of their higher density (usually over 1 g/cm<sup>3</sup>) and combustion value.

Polycyclic and caged hydrocarbons with small rings are promising propellants, and their heats of combustion can be predicted by quantum-chemical calculations [148]. Molecular design, shape-selective syntheses, and blending technology are key paths for successful development of better fuels. The synthesis of high-density liquid hydrocarbon fuels and their applications has made substantial progress over the past two decades [149]. This includes a description of feedstock, synthesis routes, properties, and cost of fuels already in use or under development.

Three high-density hydrocarbons with the gross chemical formulas of  $C_{10}H_{16}$  (C10),  $C_{15}H_{22}$  (C15), and  $C_{20}H_{28}$  (C20) were synthesized using dicyclopentadiene as feedstock [150]. The density of the fuels increased in the order of increasing number of carbon atoms C10, C15, and C20, whereas the low-temperature properties showed the inverse tendency. To obtain higher density and acceptable low-temperature property, binary and ternary mixtures of these fuels were prepared. The dependence of density and viscosity on the composition of blends was analyzed, and an equation was derived to predict the density of mixtures. C10 can improve the low-temperature properties of mixtures, whereas C20 can enhance the density. According to the density-viscosity-composition ternary diagrams, an optimized blending composition of  $C15 \geq 75 \text{ mass-}\%$ ,  $C20 \leq 20 \text{ mass-}\%$ , and  $C20 \leq 5 \text{ mass-}\%$  was selected. The resulting fuel had a density above  $1.0 \text{ g/cm}^3$  at  $288 \text{ K} = 15^\circ\text{C}$ , volumetric heat of combustion higher than  $42 \text{ MJ/L}$ , viscosity less than  $500 \text{ mm}^2 \text{ s}^{-1}$  (at  $233 \text{ K} = -40^\circ\text{C}$ ), and pour point less than  $203 \text{ K} = -70^\circ\text{C}$ , which is very promising for future propulsion applications.

Two polycyclic alkane-based, high-density, thermally stable hydrocarbon fuels for liquid fuel ramjet applications, designated DPCR-2 and DPCR-3, were prepared from processed special petroleum fraction DPCR-1 by addition of decalin and JP-10 or RJ-4 [151]. These fuels were subjected to detailed physicochemical characterization and were found to have improved density ( $0.844$  to  $0.846 \text{ g/cm}^3$  at  $293 \text{ K} = 20^\circ\text{C}$ ), low aromatic content ( $<5\%$ ), low sulfur content, and high flash point ( $>335 \text{ K} = >62^\circ\text{C}$ ). These fuels exhibited better engine performance properties than aviation turbine fuel (ATF/Jet A-1). The theoretical as well as experimental ramjet performance factors such as characteristic velocity and chamber pressure for both the fuels were higher than ordinary Jet-A1 and comparable with similar high-density T-6 fuel.

## 15 Terpenes

Terpenes are a large and diverse class of naturally occurring hydrocarbons, produced by a variety of plants, particularly conifers, and by some insects [152, 153]. The name turpentine indicates a plant-derived oil, often extracted by steam distillation. Steroids, for example, are derivatives of the triterpene squalene, including sex hormones, cholesterol, and vitamin  $D_3$ . Terpenes and terpenoids are the primary constituents of the essential oils extracted from many types of plants. There are hundreds of other uses for essential oils, and one would not want to use them as fuels in rockets or other combustion engines unless there is an objective to use replenishable, renewable, nature-derived fuels (biofuels) as opposed to fossil fuels that spew out more carbon dioxide into Earth's atmosphere [154, 155]. High-density terpene dimer fuels can be mixed with JP-8, JP-10 [156], or hydrogenated pinene.

## 15.1 Pinene

Pinene,  $C_{10}H_{16}$ , CAS RN [80-56-8], is a bicyclic monoterpene natural hydrocarbon. There are two structural isomers of pinene found in nature:  $\alpha$ -pinene and  $\beta$ -pinene. The two isomers of pinene are the major constituents of turpentine. The use of pinene as a biofuel in spark ignition engines and as a rocket fuel has been explored.

### 15.1.1 Physical Properties of Pinene

$\alpha$ -pinene has a density of  $0.86 \text{ g/cm}^3$  at 288 K (15°C) and  $0.8539 \text{ g/cm}^3$  at 298 K, a melting point of 211–218 K (−62 to −55°C = −80 to −67°F), and a boiling point of 428–429 K (155–156°C = 311–313°F).  $\alpha$ -pinene has a refractive index of  $n_D^{25} = 1.4631$ .  $\beta$ -pinene has a density of  $0.8667 \text{ g/cm}^3$  at 298 K with a refractive index of  $n_D^{25} = 1.4768$ .  $\alpha$ -pinene boils at 429 K (155.9°C), and  $\beta$ -pinene boils at 439 K (166°C) [157]. The enthalpy of vaporization of  $\alpha$ -pinene is 45.4 kJ/mol at 298 K and 43.4 kJ/mol at 308 K [158].

### 15.1.2 Chemical Properties of Pinene

Because of ring strain, pinenes have a higher heating value than linear molecules of similar molecular weights, and dimerization can effectively increase their fuel density considerably. Catalytic  $\beta$ -pinene dimerization fuels can be used as high-energy-density fuels.  $\beta$ -pinene condensation was performed to obtain dimers, which are candidates for use in renewable jet fuels [159]. To suppress the production of oligomers composed of more than two pinene units, which are undesirable in liquid fuels because of their high boiling temperatures and viscosities, the pore width of the silica-alumina aerogel catalysts was modified, and their surfaces were treated chemically. The chemical treatment of the catalyst surface improved the selectivity of fuel-grade dimer production and suppressed oligomer formation. Pinene trimers are not appropriate for use in liquid fuels because of their high viscosity and high boiling temperatures.  $\alpha$ -pinene,  $\beta$ -pinene, and crude turpentine give similar product distribution in isomerization/dimerization [160].

In the presence of Al-MCM-41 mesoporous catalyst, both  $\alpha$ - and  $\beta$ -pinenes are quickly transformed into isomerized products, which then couple to form homodimers and heterodimers [161]. Lewis acid sites are active in triggering both the isomerization and dimerization reactions, but weak Brønsted acid sites seem inactive for the dimerization. Al-MCM-41 has greater activity than many other microporous and layered materials and can be easily regenerated.

## 15.2 Other Terpenes

The heat of combustion of several terpenes was determined in a bomb calorimeter [162]. The heats of combustion were as follows:  $\alpha$ -pinene, 6205 kJ/mol (1483 kcal/mol);  $\beta$ -pinene, 6213 kJ/mol (1485 kcal/mol); and d-limonene, 6167 kJ/mol (1474 kcal/mol).

3-cyclopropylnorcarane is a high-energy fuel that can be prepared by reaction of 4-vinylcyclohexene with a carbene generator [163]. It has a three-membered ring fused to a cyclohexyl ring and a loose cyclohexyl group attached by a conventional C—C bond. It has a density of 0.89967 g/cm<sup>3</sup> and a net heat of combustion of 43.03 MJ/kg (18514 BTU/lb).

## 15.3 Hydrocarbon Fuels Derived from Naturally Occurring Plant Materials

A liquid fuel blend consisting of natural oil products carene (a distillation fraction of turpentine) and cardanol (a distillation product of cashew nutshell liquid [CNSL]) in a 70 : 30 mixture ratio (mass ratio) has been evaluated as a replacement for the aromatic amine/aliphatic amine fuel mixture G-Fuel that was used in the Prithvi missile in India. It is hypergolic with red fuming nitric acid (RFNA) and dinitrogen tetroxide (NTO). This fuel was supposed to have lower freezing point, higher boiling point, higher density, and higher density impulse compared with other storable fuels. The addition of norbornadiene would increase the performance further. A fuel blend consisting of 40 carene/40 norbornadiene/20 cardanol has been tested as a replacement for RFNA/G-Fuel [164–169]. 3-carene has better storage stability than  $\alpha$ - and  $\beta$ -pinenes. It has less of a tendency to form resins during storage but can also be polymerized on command to form a resin.

The low-temperature properties of high-density terpene dimer fuels and fuel mixtures with hydrogenated pinene, JP-8 and JP-10, have been studied using shear viscometry and thermomechanical analysis [170]. Neat terpene dimers have a viscosity of  $3.94 \times 10^3$  mPa s at 263 K (−10 °C), while 50 : 50 mixtures with JP-10, RJ-4, pinane, and JP-8 have viscosities two to three orders of magnitude lower, at 23.9, 53.0, 24.9, and 3.7 mPa s, respectively. Blending conventional fuels with terpene dimers is an effective strategy for mitigating the high viscosity of the C<sub>20</sub> molecules. In addition, blending these renewable fuels with conventional jet fuel (JP-8) imparts both a higher density and an improved volumetric net heat of combustion while maintaining an acceptable low-temperature viscosity compared to JP-8 alone.

## 16 Quadricyclane

Quadricyclane, also known as quadracyclane, QC,  $C_7H_8$ , quadricyclo[2.2.1.0<sup>2,6</sup>.0<sup>3,5</sup>]-heptane, tetracyclo[2.2.1.0<sup>2,6</sup>.0<sup>3,5</sup>]heptane, CAS RN [278-06-8], is a seven-membered bridged-ring structure containing two cyclopropyl, one cyclobutyl, and one cyclopentyl ring. It is a liquid that is stable at room temperature with a low vapor pressure and boils at 381 K (108 °C) at 740 mm Hg. Isomerization of quadricyclane proceeds slowly at low temperatures without the use of a catalyst. The unusual reactivity of QC is due to ring strain, and one of the first steps of conversion is cleavage of the C2-C6 cyclopropyl bond. It easily undergoes photochemical, electrochemical, or thermal conversion to its lower-energy-level valence isomer, 2,5-norbornadiene.

When converting back to norbornadiene via irradiation, quadricyclane's ring strain energy is liberated in the form of heat ( $\Delta H = -89$  kJ/mol). This reaction has been proposed to store solar energy. However, the absorption edge of light does not extend past 300 nm, whereas most solar radiation has wavelengths longer than 400 nm. Quadricyclane undergoes thermal decomposition at relatively low temperatures (<673 K = 400 °C). This property limits its applications because propulsion systems may operate at temperatures exceeding 773 K = 500 °C.

Quadricyclane has been identified as a possible replacement for, or additive to, kerosene-based rocket propellant RP-1 or RP-2. Density, viscosity, thermal conductivity, heat capacity, flash point, purity, 90-day aging, high temperature decomposition, impact sensitivity, friction sensitivity, and detonation sensitivity (card gap) have been measured [171, 172]. Thermal decomposition and rapid compression sensitivity test results indicated that quadricyclane can be easily handled as a liquid propellant fuel and should have performance advantages over RP-1. However, since the performance and physical properties of quadricyclane differ from those of RP-1, implementation of QC would require some modification of current rocket engine hardware.

The performance of quadricyclane as a rocket fuel was tested in a 220-N (50-lbf) rocket engine with LOX as the oxidizer in a side-by-side test in comparison to RP-1 [30]. Other fuels tested in that series were bicyclopropylidene, 2-azidoethyldimethylamine, and 1,7-octadiyne. The density of quadricyclane is 17% higher than that of RP-1, and the specific impulse is better. This yields a 17% fuel tank volume and an approximate 10% propellant volume benefit to a launch vehicle. The results of this fuel test warrant scaling to higher thrust levels and additional tests.

### 16.1 Preparation of Quadricyclane

In the presence of a catalyst, norbornadiene is converted into quadricyclane via ~300 nm UV radiation. Quadricyclane can be synthesized with high yield and selectivity, close to the theoretical value, by irradiation of norbornadiene (bicyclo[2.2.1]hepta-2,5-diene) in a photochemical reactor with a high-pressure mercury

vapor lamp and in the presence of a small amount of Michler's ketone (bis-4,4'-dimethylaminobenzophenone) or ethyl Michler's ketone [173].

Synthesis of quadricyclane from norbornadiene

Other sensitizers, such as acetone, benzophenone, acetophenone, etc., may be used but with a lesser yield [174].

The reversible photoisomerization of norbornadiene/quadricyclane has been proposed to store solar energy in power plants. A large number of catalysts have been identified to accelerate this reaction or drive it in the desired direction. When converting back to norbornadiene via irradiation, quadricyclane's ring strain energy is liberated in the form of heat ( $\Delta H = -89 \text{ kJ/mol}$ ) [175, 176].

The quadricyclane yield is higher for freshly distilled norbornadiene, but commercial reagents will suffice [177]. A sensitizer, such as a substituted diaminobenzophenone having a solubility in norbornadiene greater than that of Michler's ketone, may be added to the norbornadiene to form a solution [178].

The photoisomerization of norbornadiene to quadricyclane was studied with petroleum ether and acetone as mixed solvents, including the influences of initial concentration, amount and type of photosensitizer, and reaction time [179]. The optimum reaction conditions were obtained as follows: room temperature, initial reaction concentration 1.0 mol/L, 6% benzophenone, UV radiation 15 h, resulting in norbornadiene conversion up to 93% and selectivity of 100%. After vacuum distillation, high-purity quadricyclane fuel (95% purity) was obtained with 73% isolated yield.

The synthesis of quadricyclane on a kilogram scale was studied without the use of any solvents [180]. After 16 h of photoisomerization reaction and further purification, the purity and yield of quadricyclane product can reach 99.5 and 96.2%, respectively. Quadricyclane is a hypergolic fuel and ignites spontaneously with either  $\text{N}_2\text{O}_4$  or white fuming nitric acid (WFNA) [181].

### 16.1.1 Catalysts for Quadricyclane Synthesis and Photoisomerization

A large number of catalysts have been identified to accelerate the photoisomerization equilibrium of norbornadiene and quadricyclane or drive it in the desired direction.

Heterogeneous titanium-containing MCM-41 materials were prepared for the photocatalytic isomerization of norbornadiene to quadricyclane with the aim of replacing homogeneous sensitizers [182]. Chemical grafting produced quantum-size  $\text{TiO}_2$  crystallites highly dispersed in the pore of MCM-41. Isomorphous substitution gener-

ated titanium species in the framework of MCM-41, but some non-framework species were formed with increasing titanium content. It was found that titanium-containing MCM-41 materials showed significantly higher photocatalytic activity than bulk  $\text{TiO}_2$ , and the framework titanium species were more active than the surface-dispersed species.

Zinc-doped and lanthanum/zinc co-doped  $\text{TiO}_2$  nanoparticles were prepared by a sol-gel method and used as the photocatalysts for the isomerization of norbornadiene to quadricyclane and has significant potential for solar energy storage and high-energy fuel synthesis [183]. The isomerization reaction over semiconductors was proposed to proceed through an exciplex (charge-transfer) intermediate.

### 16.1.2 Quadricyclane Synthesis by Photoisomerization

Quadricyclane can be made by photoisomerization of norbornadiene using transition metal-doped  $\text{TiO}_2$  [184]. The photoreactivity is correlated with the surface lattice oxygen, and a mechanism was proposed to explain the photoisomerization and role of iron dopant. Under UV irradiation, the transition metal ions can improve the photoisomerization activity in order of decreasing activity  $\text{V} > \text{Fe} > \text{Cr}$  [185, 186].

## 16.2 Physical Properties of Quadricyclane

The physical properties of quadricyclane are listed in Table 21.

**Table 21:** Physical properties of quadricyclane.

| Property                                         | SI units                               | Other units                                                                                | References     |

### 16.2.1 Density of Quadricyclane

The density of quadricyclane as a function of temperature is illustrated in Figure 17. This figure compares density predictions from two different molecular orbital mechanics calculations with measured data. The measured density of three different samples of quadricyclane from three different suppliers is listed in Table 22. The data from Table 22 are illustrated in Figure 18.

**Figure 17:** Predicted and measured density of quadricyclane. (Reproduced and modified from [190] with permission of Dr. Tim Kokan 3 July 2020.)

**Table 22:** Density of three different samples of quadricyclane.

| Temperature |    | Aldrich           | EniChem (small can) | EniChem (45 kg drum) |
|-------------|----|-------------------|---------------------|----------------------|
| K           | °C | g/cm <sup>3</sup> |                     |                      |
| 283         | 10 | 0.9944            | 0.9897              | 0.9894               |

### 16.2.2 Viscosity of Quadricyclane

The kinematic viscosity of quadricyclane as a function of temperature is illustrated in Figure 19. This figure compares viscosity predictions from molecular orbital mechanics calculations with measured data. Experimental data for the kinematic viscosity of quadricyclane as a function of temperature are illustrated in Figure 20.

**Figure 19:** Predicted and measured kinematic viscosity of quadricyclane. (Reproduced and modified from [190] with permission of Dr. Tim Kokan, 3 July 2020.)

**Figure 20:** Kinematic viscosity of quadricyclane as a function of temperature. (Reproduced and modified from [172].)

### 16.2.3 Thermal Conductivity of Quadricyclane

The thermal conductivity of quadricyclane as a function of temperature is illustrated in Figure 21. This figure compares thermal conductivity predictions from molecular orbital mechanics calculations with measured data. Table 23 lists thermal conductivity of quadricyclane in comparison to that of RP-1.

**Figure 21:** Predicted and measured thermal conductivity of quadricyclane. (Reproduced and modified from [190] with permission of Dr. Tim Kokan, 3 July 2020.)

**Table 23:** Thermal conductivity of quadricyclane in comparison to that of RP-1.

|             |     | Quadricyclane (EniChem)           |                                                       | RP-1                              |                                                       |

### 16.2.4 Thermodynamic Properties of Quadricyclane

The enthalpy of vaporization of quadricyclane is  $36.99 \pm 0.02$  kJ/mol ( $8.84 \pm 0.004$  kcal/mol). The heat of combustion of quadricyclane is  $348.7 \pm 1.1$  kJ/mol ( $83.34 \pm 0.26$  kcal/mol). The enthalpy of formation of liquid quadricyclane is  $+216.3 \pm 1.1$  kJ/mol ( $+51.70 \pm 0.26$  kcal/mol) [189]. This enthalpy of formation for quadricyclane differs from a value reported earlier,  $\Delta H_f = +302.1$  kJ/mol =  $+72.2$  kcal/mol [191].

A technique for determining thermophysical properties of rocket engine propellants used a combination of three different computational methods to predict these properties [190, 192–194]. Quantum mechanics and molecular dynamics methods were used to model new propellants at a molecular level in order to calculate density, enthalpy, and entropy. Additivity methods were used to calculate the kinematic viscosity and thermal conductivity of new propellants. This technique was validated by comparing results for two propellants: quadricyclane and 2-azido-*N,N*-dimethylethanamine (DMAZ). In each case, the new technique was better than the best current computational methods at accurately matching the experimental data of the two propellants. Table 24 gives a comparison of the enthalpies and entropies of formation of quadricyclane and DMAZ, two candidate hypergolic fuels. See also [189].

**Table 24:** Thermodynamic properties of liquid DMAZ and liquid quadricyclane

| Compound      | Enthalpy of formation $\Delta H_f$ |          | $\Delta S_f$ at 101 kPa             | $\Delta S_f$ at 1 atm                  |
|---------------|------------------------------------|----------|-------------------------------------|----------------------------------------|
|               | kJ/mol                             | kcal/mol | J mol <sup>-1</sup> K <sup>-1</sup> | cal mol <sup>-1</sup> °C <sup>-1</sup> |

Data source: [190]

### 16.2.5 Molecular Structure of Quadricyclane

Quadricyclane has a very high strain energy, 393 kJ/mol (94 kcal/mol), because of the degree of stressing of carbon-carbon bonds away from tetrahedral bonds inside its molecule. The molecular structure of quadricyclane is illustrated in Figure 22.

Figure 22: Molecular structure of quadricyclane.

## 16.3 Chemical Properties of Quadricyclane

### 16.3.1 Isomerization of Quadricyclane

The energy-releasing isomerization of quadricyclane back to norbornadiene was thoroughly investigated as part of a photochemical energy-storage scheme. While the thermal barrier for reversion of quadricyclane back to norbornadiene is relatively high, the energy-releasing conversion of quadricyclane to norbornadiene can be achieved readily via a free-radical-cation chain reaction initiated by one-electron oxidations [195]. The difference in enthalpy of formation of the two hydrocarbons is 96 kJ/mol (23 kcal/mol).

Quantum mechanical *ab initio* calculations were performed to explain the thermal isomerization of quadricyclane to norbornadiene, which occurs via a forbidden pathway [196]. The predicted activation barrier was 142 kJ/mol (34 kcal/mol), consistent with the 138 kJ/mol (33 kcal/mol) measured by earlier investigators. The transition state has a biradical character. The reaction is highly asynchronous, with one bond cleaving entirely before the transition state and the second bond cleaving afterward on the intrinsic reaction coordinate.

### 16.3.2 Reactions (Other than Isomerization) of Quadricyclane

Quadricyclane can undergo cycloaddition reactions with olefins, acetylenes, carbonyl, nitrogen, sulfur-containing compounds, carbenes, and silenes, along with cycloaddition reactions involving transition metals, photochemical transformations, ionic reactions (electrophilic and nucleophilic), oxidation, and reduction [197].

### 16.3.3 Thermal Decomposition of Quadricyclane

The pyrolysis/combustion mechanisms of quadricyclane were studied in an apparatus consisting of a resistively heated reactor (1000 °C) for flow and static pyrolysis studies, a pulsed IR laser pyrolysis source, and a gas chromatographic analyzer with flame ionization, thermal conductivity, and mass spectrometric detectors [198]. The flow reactor and the gas chromatographic analysis system were validated at 978 and 1033 K (705 and 760 °C) with the well-established pyrolysis of propane in helium. Gas-phase thermal decomposition studies of quadricyclane and its decomposition products were conducted in the presence and in the absence of oxygen at atmospheric pressure in helium.

Pyrolysis and isomerization of the  $C_7H_8$  isomers quadricyclane, norbornadiene, cycloheptatriene, and toluene have been studied in a micro-flow tube reactor with detection/isomer identification by guided ion beam tandem mass spectrometry [199]. This methodology permits pyrolysis studies with product isomer identification with samples of only a few milligrams. The samples were pre-mixed with buffer gas and then passed through a temperature-controlled flow tube reactor with millisecond residence time. The sample/pyrolysis products exiting the flow tube were ionized by methane chemical ionization, and both mass spectra and low-energy collision-induced dissociation were used to determine the composition. Quadricyclane began to decompose at ~500 K, and the dominant decomposition processes were the acetylene elimination and isomerization to toluene, with a small amount of norbornadiene production.

A laboratory-scale flow reactor was developed to subject small amounts (approximately 1 mL) of deoxygenated fuels to controlled conditions of temperature and residence-time-at-temperature at constant pressure (34 atm) in the liquid or supercritical phase [31]. The reactor was made from 316 stainless-steel high-performance liquid chromatography (HPLC) tubing. Using an inline analytical system, as well as offline chromatographic analysis of products, the thermal stability of the parent material and the thermal fragmentation products of each fuel were measured. Quadricyclane and bicyclopentylidene showed only marginal thermal stability, with major decomposition occurring before 400 °C (~3 s residence time). Other fuels (JP-10, RP-1, RG-1, RJ-6, and RJ-7) showed excellent thermal stability with little decomposition even at 873 K (600 °C). Results showed the pyrolytic stability of candidate materials relative to each other and provided insights into the mechanisms of thermal decomposition for specific fuel candidates.

Pyrolysis experiments of quadricyclane at 473–1073 K and 1.0–2.0 MPa were conducted in a micro-reactor equipped with online GC-MS/flame ionization detection to investigate the dependence of pyrolysis mechanism on pressure [200]. It was found that quadricyclane first isomerizes into 2,5-norbornadiene (NBD) below 598 K under 1.0 MPa with an activation energy of  $68.50 \pm 5.95$  kJ/mol, and then NBD decomposes through three major pathways: the retro-Diels-Alder reaction to acetylene plus cyclopentadiene, the isomerization into 1,3,5-cycloheptatriene, and the isomerization

into toluene. The high pressure inhibits the isomerization of quadricyclane into NBD and the retro-Diels-Alder reaction of NBD, but it promotes the isomerization reactions of NBD into 1,3,5-cycloheptatriene and into toluene. The further reactions of cyclopentadiene and toluene produce small molecules and aromatic products, mainly from the combination of cyclopentadiene and cyclopentadienyl. Based on the detailed analysis of the decomposition products and kinetics, a possible kinetic mechanism of quadricyclane pyrolysis was then proposed.

#### 16.4 Other Quadricyclane Derivatives

Attempts have been made to synthesize more energetic fuels by attaching explosophoric groups, such as azido groups, to quadricyclane [201, 202].

#### 16.5 Safety Properties of Quadricyclane

The flash point of quadricyclane is at 275 K (+2°C) [187].

#### 16.6 Toxicity of Quadricyclane

Quadricyclane caused 100% mortality in male Fischer 344 rats within 24 h following gavage at 3.5 g/kg [203, 204]. The LC<sub>50</sub> is somewhere between 1.2 and 3.5 g/kg. Gavage treatment with a quadricyclane/kerosene mixture (70% quadricyclane, 30% kerosene), similar to the proposed rocket fuel mixture, produced toxic effects at a dose level below the U.S. Environmental Protection Agency (EPA) limit test. No treatment-related deaths occurred in rabbits following a 24-h dermal exposure to the EPA limit dose of 2 g test material/kg body weight.

Measurements of the inhalation toxicity of quadricyclane in acute 4-h exposures of male Sprague-Dawley rats to QC vapor resulted in an LC<sub>50</sub> value of 0.78 mg/L [205]. Subchronic (2-week) inhalation exposure of groups of male and female Sprague-Dawley rats at 0.0, 0.025, 0.075, and 0.25 mg/L quadricyclane resulted in no mortality. Body weights of exposed rats were significantly less than those of the controls after 10 exposures. No exposure-related gross lesions were noted at necropsy. A 90-d general toxicity/reproductive screen using concentrations of 0.0, 0.01, 0.025, and 0.10 mg/L quadricyclane produced no significant exposure-related differences in the reproductive or litter parameters measured. The only lesion noted at necropsy was minimal pulmonary inflammation in the lungs of the mid-concentration and high-concentration male rats. Significant treatment-related increases in brain dopamine and 5-hydroxytryptamine levels were detected in all quadricyclane-exposed rats.

The low-concentration level of 0.01 mg/L quadricyclane represents a no observable adverse effect level (NOAEL).

The biodegradation and hydrolysis of quadricyclane in water yielded two hydroxy-substituted compounds, tricyclic or bicyclic alcohols [206]. Both quadricyclane and its hydroxy-substituted compounds were toxic to bacterial cultures. LC50 concentrations were 0.88 and 0.82 mM for *Pseudomonas aeruginosa* and *Pseudomonas putida*, respectively.

## 16.7 Applications of Quadricyclane

The use of quadricyclane as a high-energy fuel, a potential replacement for RP-1 or RP-2, has been investigated, but due to a limited supply, QC has never found a practical application. Quadricyclane as a rocket fuel can be mixed with RP-1 or *n*-hexane [207].

Quadricyclane is hypergolic with NTO, in particular if it is used as a suspension of sub-micron-sized boron particles in quadricyclane [180, 181]. The ignition-delay time of NTO/quadricyclane was 29 ms, which decreased to 18 ms by addition of boron nanoparticles to the fuel. Quadricyclane is hypergolic with WFNA, NTO, and high-test peroxide (HTP) [208].

The heat of combustion of quadricyclane can be increased by dissolving acetylene in the fuel. The solubility of acetylene in quadricyclane can be enhanced by adding triethylamine [209]. The solubility of acetylene in quadricyclane at 298 K and pressures up to 200 kPa was studied. The solubility of acetylene in the presence of triethylamine showed that such additives could significantly increase the solubility of acetylene in the fuel.

## 17 Norbornane

Norbornane, also known as C<sub>7</sub>H<sub>12</sub>, bicyclo[2.2.1]heptane, CAS RN [279-23-2], is an organic compound and a saturated hydrocarbon. It is a crystalline, readily subliming compound with a melting point of 358 to 361 K (85 to 88 °C). The carbon skeleton is derived from a cyclohexane ring with a methylene bridge in the 1,4-position, and thus it is a bridged bicyclic compound (Figure 23). This compound is a prototype of the class of strained bicyclic hydrocarbons. Norbornane is prepared by reduction of norbornene.

Figure 23: Molecular structure of norbornane.

### 17.1 Physical Properties of Norbornane

Norbornane melts at 358 to 361 K (85 to 88 °C) and sublimes readily. The vapor pressure of crystalline norbornane in the temperature range 284–327 K can be calculated from the equation

$$\log P = (-2097.5/T) + 8.479$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin [2].

The enthalpy of formation of solid norbornane is  $-92.1 \pm 2.2$  kJ/mol ( $-22.01 \pm 0.52$  kcal/mol). The enthalpy of formation of norbornane vapor is  $-51.96 \pm 2.9$  kJ/mol ( $-12.42 \pm 0.70$  kcal/mol). The enthalpy of vaporization of norbornane is 40.12 kJ/mol (9.59 kcal/mol) [188].

The thermal decomposition of norbornane (dissolved in benzene) has been studied in a jet-stirred reactor at temperatures between 873 and 973 K, at residence times ranging from 1 to 4 s, and at atmospheric pressure, leading to conversions from 0.04 to 22.6% [210]. A total of 25 reaction products were identified and quantified by gas chromatography, among which the main ones were hydrogen, ethene, and 1,3-cyclopentadiene. Reactions involved in a proposed mechanism include unimolecular initiations by C–C bond scission of norbornane, generation of diradicals, the reactions of transfer and propagation of norbornyl radicals, the reactions of benzene, and cross-coupling reactions.

### 17.2 Other Norbornane Derivatives

Spiro[cyclopentane-1,2'-norbornane],  $C_{11}H_{18}$ , has been synthesized by a one-pot Mannich-Diels-Alder reaction from cyclopentanone, formaldehyde, and cyclopentadiene [211]. It has a density of 0.952 g/cm<sup>3</sup> at 293 K (20 °C), a freezing point of 220 K (–53 °C), and a net heat of combustion of 42.21 MJ/kg.

## 18 Norbornene

Norbornene,  $C_7H_{10}$ , bicyclo[2.2.1]hept-2-ene, CAS RN [498-66-8], is a bridged cyclic hydrocarbon. It is a white readily subliming solid with an unpleasant odor. The molecule consists of a cyclohexene ring with a methylene bridge between carbons 1 and 4. The molecule carries a double bond that induces significant ring strain and significant reactivity. Norbornene can be prepared by a Diels-Alder reaction of cyclopentadiene and ethene.

It has a melting point of 315 to 319 K (42 to 46 °C = 108 to 115 °F) and a boiling point of 369 K (96 °C = 205 °F). The heat of combustion of norbornene is  $4213 \pm 1.7$  kJ/mol ( $1007.04 \pm 0.40$  kcal/mol). The enthalpy of formation of liquid norbornene is  $+29.7 \pm 1.7$  kJ/mol ( $+7.09 \pm 0.40$  kcal/mol). The enthalpy of vaporization of norbornene is  $33.6$  kJ/mol ( $8.03$  kcal/mol) [188]. Photochemical dimerization of norbornene catalyzed by copper(I) chloride leads to a dimer with a cyclobutane ring, which can be used as a rocket fuel [212].

## 19 Norbornadiene

Norbornadiene,  $C_7H_8$ , 2,5-norbornadiene, bicyclo[2.2.1]hepta-2,5-diene, CAS RN [121-46-0], is a homocyclic hydrocarbon that achieved most interest because of its ability to isomerize to quadricyclane (see Section 15.1).

### 19.1 Preparation of Norbornadiene

Norbornadiene can be prepared by a Diels-Alder reaction between cyclopentadiene and acetylene:

The dimers and trimers of norbornadiene have a unique polycyclic strained structure and are useful as high-density fuels. A systematic study of the synthesis of norbornadiene from dicyclopentadiene and acetylene under pressure investigated the effects of various operating parameters on product distribution [213]. The optimum conditions for the synthesis were as follows: temperature, 563 K = 290 °C; residence period, 16 min; mol ratio of  $C_2H_2:N_2$ : dicyclopentadiene, 1:1:0.4; and initial pressure at ambient temperature, 0.8 MPa. Under these conditions the conversion of norbornadiene was 41% on the basis of dicyclopentadiene consumed. The loss of dicyclopentadiene due to polymerization was estimated from the material balance.

## 19.2 Physical Properties of Norbornadiene

### 19.2.1 Freezing Point of Norbornadiene

Norbornadiene freezes at 254 K ( $-19\text{ °C} = -2\text{ °F}$ ).

### 19.2.2 Boiling Point of Norbornadiene

Norbornadiene boils at 362 K ( $89\text{ °C} = 192\text{ °F}$ ).

### 19.2.3 Density of Norbornadiene

Norbornadiene has a density of  $0.906\text{ g/cm}^3$  at 293 K.

### 19.2.4 Thermodynamic Properties of Norbornadiene

The heat of combustion of norbornadiene is  $311.1 \pm 1.0\text{ kJ/mol}$  ( $74.35 \pm 0.24\text{ kcal/mol}$ ). The enthalpy of formation of liquid norbornadiene is  $+178.7 \pm 1.00\text{ kJ/mol}$  ( $+42.72 \pm 0.24\text{ kcal/mol}$ ). The enthalpy of vaporization of norbornadiene is  $32.93 \pm 0.08\text{ kJ/mol}$  ( $7.87 \pm 0.02\text{ kcal/mol}$ ) [188].

### 19.2.5 Molecular Structure of Norbornadiene

The molecular structure of norbornadiene is illustrated in Figure 24.

Figure 24: Molecular structure of norbornadiene.

### 19.3 Chemical Properties of Norbornadiene

#### 19.3.1 Thermal Stability of Norbornadiene

##### 19.3.1.1 Isomerization of Norbornadiene

In the past, the isomerization of norbornadiene to quadricyclane was investigated mostly as an energy-storage reversible reaction and not so much as a method for producing a rocket propellant. The valence photoisomerization of norbornadiene to quadricyclane or quadricyclane can be catalyzed by copper(I) salts [214, 215], copper complexes [216], orthometalated transition-metal complexes [217], rhodium(III) salts [218], or zeolites [219].

Pyrolysis and isomerization of the  $C_7H_8$  isomers norbornadiene, quadricyclane, cycloheptatriene, and toluene have been studied in a micro-flow tube reactor with detection/isomer identification by guided ion beam tandem mass spectrometry [199]. This methodology permits pyrolysis studies with product isomer identification with samples of only a few milligrams. The samples were premixed with buffer gas and then passed through a temperature-controlled flow tube reactor with millisecond residence time. The sample/pyrolysis products exiting the flow tube were ionized by methane chemical ionization, and both mass spectra and low-energy collision-induced dissociation were used to determine the composition. For the experimental residence time, decomposition of norbornadiene sets in at  $\sim 600$  K. The dominant decomposition processes are acetylene elimination via a retro-Diels-Alder reaction and isomerization to toluene. See also [220].

##### 19.3.1.2 Oligomerization of Norbornadiene

Under the influence of zeolites, the dimerization of norbornadiene can go beyond the linking of two norbornadiene molecules, resulting in higher oligomers that can also be used as high-density fuels [221].

## 20 Dinorbornadiene

Norbornadiene readily dimerizes to form dinorbornadiene. Dinorbornadiene was an intermediate product in the synthesis of Shellldyne-H, the main ingredient of RJ-5. The storage stability of this bridged cycloparaffin was improved by hydrogenating all unsaturated C=C bonds, resulting in perhydrodinorbornadiene, the main ingredient of Shellldyne-H and RJ-5.

## 21 Perhydrodinorbornadiene

Perhydrodinorbornadiene, also known as dihydrodinorbornadiene, hexacyclic dihydrodinorbornadiene,  $C_{14}H_{18}$ , is formed by hydrogenation of dinorbornadiene. A mixture of structural isomers of perhydrodinorbornadiene is the main ingredient of Shellldyne-H and RJ-5. The properties of RJ-5 are discussed in the chapter “Ramjet Fuels.” The molecular structures of two valence isomers are shown in the following images (Figure 25). These are the most complex structures shown in this entire book.

There are eight structural isomers of perhydrodinorbornadiene, so only two typical ones are shown here.

Hexacyclic *exo,exo*-dihydrodinorbornadiene

Hexacyclic *endo,endo*-dihydrodinorbornadiene

**Figure 25:** Molecular structures of HXX (top) and HNN (bottom) perhydrodinorbornadiene (DHDNBD).

## 21.1 Preparation of Perhydrodinorbornadiene

Perhydrodinorbornadiene can be prepared by reduction of dinorbornadiene with hydrogen over a 10% palladium/carbon catalyst in methylcyclohexane at 373 K and 68 atm [222].

## 21.2 Physical Properties of Perhydrodinorbornadiene

### 21.2.1 Melting Point of Perhydrodinorbornadiene

One of the most remarkable findings of a study on polycyclic hydrocarbons was the observation of two distinct melting points for the HNN and HXX isomers of perhydrodinorbornadiene (PHDNBD) [223]. This was first detected in measuring the melting point of pure HNN, where it was found that about half of the time the sample would melt at 273.65 K (0.5 °C), and the other half of the time it would melt at 280.65 K (7.5 °C). With the HXX isomer, if the melting point was measured immediately after crystallization, it was found to be 284.4 K (11.3 °C), whereas if the crystallized sample was held for 1 to 2 h near dry-ice temperature, it was found to be 290.1 K (17.0 °C). The explanation for this phenomenon is that there are two crystalline forms or polymorphs of the HNN and of the HXX isomers, which were designated as “low melting point” and “high melting point,” respectively. It can be shown from thermodynamics that in the vicinity of the lower melting point, the low-melting-point form is metastable with respect to the high-melting-point form. Seeding with high-melting-point HNN crystals causes crystallization of only high-melting-point HNN, which melts at 253.6 K (−19.5 °C).

### 21.2.2 Density of Perhydrodinorbornadiene

For single data points, the density of HNN isomer at 298 K is 1.085 g/cm<sup>3</sup>, compared to a density of 1.073 g/cm<sup>3</sup> for the HXX isomer [224]. Densities of the purified liquid PHDNBD isomers and their mixtures with *exo*-tetrahydrodicyclopentadiene (THDCPD) are linear functions of temperature. Table 25 gives the parameters obtained from least squares fits to the equation

$$\rho = \rho_0 - Bt$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $t$  is the temperature in °C. The parameters for density equations for HNN, HXX, isomer I, and *exo*-THDCPD are given in Table 25.

**Table 25:** Parameters for density equations for HNN, HXX, isomer I, and *exo*-THDCPD.

| Compound                  | Temperature range |            | $\rho_0$ | $B \times 10^4$ | Standard deviation |
|---------------------------|-------------------|------------|----------|-----------------|--------------------|
|                           | K                 | °C         |          |                 |                    |
| HNN                       | 223–323           | –50 to +50 | 1.105    | 7.49            | 0.0004             |
| HXX                       | 259–323           | –14 to +50 | 1.098    | 7.50            | 0.0004             |
| Isomer I                  | 263–323           | –10 to +50 | 1.097    | 7.81            | 0.0002             |
| <i>exo</i> -THDCPD run I  | 219–323           | –54 to +50 | 0.951    | 7.60            | 0.0003             |
| <i>exo</i> -THDCPD run II | 218–323           | –55 to +50 | 0.951    | 7.60            | 0.0004             |

Data source: [223]

### 21.2.3 Vapor Pressure of Perhydrodinorbornadiene

The vapor pressure of perhydrodinorbornadiene is similar to that of RJ-5, which was calculated to be 0.96 kPa (0.00952 atm = 7.2 mm Hg) at 366.7 K (200 °F).

### 21.2.4 Viscosity of Perhydrodinorbornadiene

Shear viscosities of four isomeric hydrogenated norbornadiene dimers and their mixtures were measured over the viscosity range 0.04–200 Ps [225]. On a logarithmic viscosity scale, all of the liquids exhibited identical temperature dependences. The combined effects of composition and temperature on the viscosity could be described accurately by a modified free-volume equation. It was found that the viscosity differences among the different isomers were due to differences in their molecular dimensions along the direction of the long axis.

Shear viscosity results are listed in Table IV from [226]. The data for HNN, HXX, isomorph I, and *exo*-THDCPD are shown in Figure 26 in the form of Arrhenius plots of  $\log \eta$  vs.  $1/T$ . These plots are typical of those observed for nearly all liquids, i.e., they are not linear, but curved.

Viscosity as a function of temperature can be expressed by the equation

$$\ln \eta = A + B/(T - T_0)$$

where  $\eta$  is the viscosity in Poise and  $T$  is the temperature in kelvin.  $A$ ,  $B$ , and  $T_0$  are constants listed in Table 26. Additional density and viscosity data are available in [226] for mixtures of the PHDNBD isomers with *exo*-THDCPD.

**Figure 26:** Viscosity of HNN, HXX, isomorph I, and *exo*-THDCPD. (Reproduced and modified from [226].)

**Table 26:** Coefficients for viscosity equations for perhydrodinorbornadiene isomers and *exo*-tetrahydrodicyclopentadiene.

| Compound                  | Temperature range |            | A      | B      | $T_0$ | Standard deviation |
|---------------------------|-------------------|------------|--------|--------|-------|--------------------|
|                           | K                 | °C         |        |        |       |                    |
| HNN                       | 223–323           | –50 to +50 | –7.168 | 850.75 | 150   | 0.0043             |
| HXX                       | 259–323           | –14 to +50 | –6.765 | 656.87 | 166   | 0.0006             |
| Isomer I                  | 263–323           | –10 to +50 | –7.041 | 768.95 | 152   | 0.0325             |
| <i>exo</i> -THDCPD run I  | 219–323           | –54 to +50 | –7.752 | 881.78 | 86    | 0.0060             |
| <i>exo</i> -THDCPD run II | 218–323           | –55 to +50 | –7.653 | 847.96 | 89    | 0.0016             |

Data source: [226]

### 21.2.5 Thermodynamic Properties of Perhydrodinorbornadiene

Enthalpies of fusion and heat capacities of crystals below the melting point and liquid above the melting point were measured with a Perkin-Elmer model DSC-2 differential scanning calorimeter (DSC) [223, 226, 227]. Table 27 lists the molar heats of fusion,  $\Delta H_f$ , of pure low-melting-point and high-melting-point HNN and HXX, along with the melting points  $T_{\text{melt}}$  determined by the American Society for Testing and Materials (ASTM) method. The  $\Delta H_f$  values are averages of between two and 13 DSC measurements carried out at a heating rate of 0.625 K/min on each crystal. Two heat capacity data are also in that table.

**Table 27:** Enthalpy of fusion and heat capacity of perhydrodinorbornadiene isomers.

| Compound       | Melting point, K | $\Delta H_f$ , cal/mol | $C_p$ , cal mol <sup>-1</sup> K <sup>-1</sup> |
|----------------|------------------|------------------------|-----------------------------------------------|
| HNN, high m.p. | 280.7 ± 0.3      | 3720 ± 50              | 11.6 ± 1.7                                    |
| HNN, low m.p.  | 273.7 ± 0.3      | 2000 ± 70              | —                                             |
| HXX, high m.p. | 290.2 ± 0.3      | 2850 ± 40              | 7.3 ± 0.7                                     |
| HXX, low m.p.  | 284.5 ± 0.3      | 3150 ± 70              | —                                             |

m.p. = melting point

Enthalpy of fusion and heat capacity results were reported previously for impure samples of HNN (96.8% by GC) and HXX (98.6% by GC). The heat of combustion of HNN is 8150 ± 1.5 kJ/mol (1948.11 ± 0.36 kcal/mol), and the heat of combustion of HXX is 8121 ± 1.9 kJ/mol (1940.88 ± 0.46 kcal/mol) [224]. The standard enthalpy of formation of liquid HNN is  $\Delta H_f^{298} = +65.1 \pm 1.7$  kJ/mol (+15.56 ± 0.40 kcal/mol), and the standard enthalpy of formation of liquid HXX is  $\Delta H_f^{298} = +39.1 \pm 1.7$  kJ/mol (+9.34 ± 0.40 kcal/mol) [224]. The standard enthalpies of formation for the same compounds in the vapor state are +134.6 ± 1.7 kJ/mol (+32.18 ± 0.41 kcal/mol) for HNN and +104.5 ± 2.1 kJ/mol (+24.97 ± 0.50 kcal/mol) for the HXX isomer. The difference between these numbers should be the enthalpy of vaporization, which we calculated as 69.5 kJ/mol for the HNN and 65.4 kJ/mol for the HXX isomer.

Isomers of the major JP-9 constituent, hydrogenated norbornadiene (RJ-5), were separated by preparative gas chromatography, and enthalpies of fusion for each were measured using a DSC [72].

### 21.2.6 Molecular Structure of Perhydrodinorbornadiene Isomers

The molecular structures of perhydrodinorbornadiene isomers are drawn in Figure 27.

**Figure 27:** Molecular structures of perhydrodinorbornadiene RJ-5 isomers. (From [226].)

### 21.3 Chemical Properties of Perhydrodinorbornadiene

Chemical synthesis of RJ-5 (perhydrodinorbornadiene) gives a mixture of many isomers. Depending on synthesis conditions, one of these isomers will be the predominant form. Three different types of “as synthesized” perhydrodinorbornadiene in which the main isomeric constituents were respectively HNN (93%), HXX (75%), and isomer I (57%) were used for a characterization of physical properties [223, 226, 227]. The main isomeric constituent of each fuel was isolated by recrystallizing it from acetone at dry-ice temperature. HNN and HXX could be purified to 99.9% (as determined by GC) in three recrystallizations, but 13 recrystallizations of isomer I gave a purity of only 97%.

### 21.4 Perhydrodinorbornadiene Mixtures

Tetrahydrodicyclopentadiene (JP-10) is used as a viscosity and melting point lowering diluent for RJ-5. An RJ-5/JP-10 mixture with 36–42 mass-% JP-10 is referred to as RJ-6 (see chapter “Ramjet Fuels”). All of the liquids studied here showed a strong tendency to supercool. Often there was considerable difficulty in inducing them to crystallize prior to measuring the melting point, particularly with those liquids blended from “as synthesized” RJ-5.

## 22 Dicyclopentadiene

Dicyclopentadiene is a precursor for the synthesis of tetrahydrodicyclopentadiene, commonly known as JP-10. Dicyclopentadiene, *exo*-tetrahydrodicyclopentadiene,  $C_{10}H_{12}$ , tricyclo[5.2.1.0<sup>2,6</sup>]deca-3,8-diene, 1,3-dicyclopentadiene, DCPD, CAS RN [77-73-6] is a white crystalline solid with a camphor-like odor with a density of  $0.98\text{ g/cm}^3$ , melting point of 305.6 K (32.5 °C), and boiling point of 443 K (170 °C).

### 22.1 Production of Dicyclopentadiene

Dicyclopentadiene is co-produced in large quantities as a side product in the steam cracking of naphtha and gas oils to ethene. The major use is in resins, particularly unsaturated polyester resins. Polymers based on polymerization of dicyclopentadiene were tested for compatibility with HTP [228]. There is an ample supply of dicyclopentadiene as a raw product for the production of JP-10 and other high-density hydrocarbons.

Dicyclopentadiene (tricyclo(5.2.1.0)deca-3,8-diene) is synthesized by a Diels-Alder reaction of cyclopentadiene. The heat of reaction of this dimerization is  $-75.4\text{ kJ/mol}$  and yields two stereo-isomer forms (*endo* and *exo*). If the exothermic reaction occurs unexpectedly during storage of cyclopentadiene, this can lead to accidents. For this reason, cyclopentadiene is traded as its dimer and de-dimerized at the point of use. But even the *endo*-dimer can cause problems. There have been several thermal runaway accidents related to uncontrolled *endo*-to-*exo* conversions [229]. The energy difference of enthalpy of formation between the two isomers was estimated as  $2.9 \pm 0.4\text{ kJ/mol}$  ( $0.7 \pm 0.1\text{ kcal/mol}$ ) based on various computational methods.

The spontaneous dimerization of cyclopentadiene at room temperature to form dicyclopentadiene proceeds to around 50% conversion in the course of 24 h and yields the *endo* isomer in a better than 95:5 *endo*:*exo* ratio as the kinetically favored product. Prolonged heating results in more complete isomerization to the *exo* isomer.

Dimerization of cycloolefins may be achieved catalytically using commercially available Fe(III) salts, and the reaction is applicable to a range of ring sizes (C5–C8) and limited ring-substitution patterns [230].

## 22.2 Physical Properties of Dicyclopentadiene

Dicyclopentadiene has a density of  $0.98 \text{ g/cm}^3$ , melting point of  $305.6 \text{ K}$  ( $32.5^\circ\text{C}$ ), and boiling point of  $443 \text{ K}$  ( $170^\circ\text{C}$ ). The vapor pressure at  $293 \text{ K}$  ( $20^\circ\text{C}$ ) is  $180 \text{ Pa}$ . The *endo* isomer is more viscous and has a higher freezing point than the *exo* isomer, and the ratio of the two isomers is not reproducible from batch to batch, which results in undesirable variations of the properties of RJ-4. For this reason, the *endo* isomers are converted to the *exo* isomer by isomerization over  $\text{AlCl}_3$  catalysts, and the isomerized fuel has the designation RJ-4I. This isomerization improves the low-temperature viscosity. The viscosity at  $233 \text{ K}$  ( $-40^\circ\text{C}$ ) is reduced from  $60 \text{ cSt}$  to  $28 \text{ cSt}$ . However, this isomerization causes a slight drop in the heating value, from  $39.0$  to  $38.5 \text{ MJ/L}$ .

## 22.3 Thermodynamic Properties of Dicyclopentadiene

Dicyclopentadiene exists in the form of two structural isomers, the *exo* and *endo* isomers. There have been several thermal runaway accidents related to this hazardous compound. It is well known that enthalpy of formation is one of the most important parameters for investigating thermal runaway reactions. The enthalpy of formation for the *endo* isomer has been characterized via computational and experimental studies; however, there was no thorough computational or experimental study on the enthalpy of formation for the *exo* isomer. Computational chemistry methods with homodesmotic reaction schemes were used to predict the enthalpy of formation for the *exo* isomer [229]. First, the computational methodology was validated by comparing predicted results of the *endo* isomer with its existing experimental value ( $+176 \pm 2 \text{ kJ/mol} = +42.2 \pm 0.6 \text{ kcal/mol}$ ). The results from high-level *ab initio*, density functional theory, and composite methods were shown to be in good agreement with the experimental value. The same methodology was then applied to predict the enthalpy of formation for the *exo* isomer. The energy difference of enthalpy of formation between two isomers was estimated at  $2.9 \pm 0.4 \text{ kJ/mol} = 0.7 \pm 0.1 \text{ kcal/mol}$  based on various computational methods. Therefore, combining the experimental and computational data, the predicted enthalpy of formation for the *exo* isomer is  $+174 \pm 2.5 \text{ kJ/mol} = +41.5 \pm 0.6 \text{ kcal/mol}$ . Thermodynamically, the *exo* isomer is about  $2.9 \text{ kJ/mol}$  ( $0.7 \text{ kcal/mol}$ ) more stable than the *endo* isomer.

## 22.4 Molecular Structure of Dicyclopentadiene

Dicyclopentadiene exists in two stereoisomers, *endo*- and *exo*-dicyclopentadiene (Figures 28 and 29).

**Figure 28:** Molecular structure of *endo*- and *exo*-dicyclopentadiene.

**Figure 29:** Molecular structure of *endo*-dicyclopentadiene.

## 22.5 Chemical Properties of Dicyclopentadiene

### 22.5.1 Reactions of Dicyclopentadiene

Above 423 K (150 °C), dicyclopentadiene undergoes a retro-Diels-Alder reaction at an appreciable rate to yield cyclopentadiene. The reaction is reversible, and at room temperature cyclopentadiene dimerizes again over the course of several hours to re-form dicyclopentadiene [231].

### 22.5.2 Hydrogenation of Dicyclopentadiene

Hydrogenation of dicyclopentadiene gives *endo*-tetrahydrodicyclopentadiene (TH-dimer), the main ingredient in JP-10 (see chapter “Jet Fuels”). It is thus a reaction that is conducted on an industrial scale.

Continued hydrogenation of dicyclopentadiene gives the saturated derivative cycloaliphatic compound  $C_{10}H_{16}$ , which can undergo acid-catalyzed rearrangement to adamantane. The Diels-Alder synthesis from cyclopentene and cyclopentadiene leads

to mixtures of both isomers of dihydrodicyclopentadiene as well as dicyclopentadiene [232].

The kinetics of dicyclopentadiene hydrogenation were investigated in a laboratory stirred autoclave using a powdered palladium catalyst [233]. The time function of reaction mixture composition for different hydrogen partial pressures, temperatures, catalyst weights, and initial concentrations of dicyclopentadiene in a cyclohexane solution was measured, and kinetic data were described using Langmuir-Hinshelwood kinetics. The kinetic rate constant of the first reaction step was 5.5 times higher with respect to the second one. Adsorption constants of unsaturated hydrocarbons are often proportional to the number of double bonds in their molecule. The values of activation energy of both consecutive reactions (25 and 18 kJ/mol) correspond to the interval typical for liquid-phase hydrogenation of unsaturated hydrocarbons.

The intrinsic kinetics of dicyclopentadiene (DCPD) hydrogenation into *endo*-tetrahydrodicyclopentadiene (*endo*-THDCPD) over Pd/Al<sub>2</sub>O<sub>3</sub> catalysts was investigated using stirred semi-batch reactors in the absence of transport limitations over ranges of temperature (358–438 K) and hydrogen pressure (0.5–3 MPa) [234]. A Langmuir-Hinshelwood-type model was proposed to fit the experimental data. The kinetic parameters were regressed by numerically integrating the differential mass balance equations for the stirred semi-batch reactors. The activation energy for the first- and second-step reactions was 7.8945 and 12.2068 kJ/mol, respectively.

Hydrogenation of DCPD into *endo*-THDCPD in the presence of a Pd/Al<sub>2</sub>O<sub>3</sub> catalyst was experimentally and theoretically studied in a quasi-adiabatic trickle-bed reactor with a diameter of 24 mm and a length of 850 mm [235]. Effects of several operating parameters, including the liquid hourly space velocity (LHSV) (6–14 h<sup>-1</sup>), hydrogen pressure (1–2 MPa), inlet liquid concentration (0.5–1.3 mol/L), and inlet temperature (319–379 K) on the trickle-bed reactor performance were investigated systematically in terms of DCPD conversions, THDCPD yields, global hydrogenation rates, and axial temperature profiles. A plug-flow model for the trickle-bed reactor incorporating partial wetting, mass and enthalpy balance, and phase equilibria behavior was developed to simulate the experimental results, based on a phenomenological pellet-scale model. A comparison of experimental and simulated results indicated that the developed model reliably predicted the performance and axial temperature profiles.

The unsteady-state operation of a trickle-bed reactor was investigated using a multi-step exothermic reaction, the hydrogenation of dicyclopentadiene in the presence of a Pd/Al<sub>2</sub>O<sub>3</sub> catalyst [236]. The influence of five operation strategies on the reactor performance was studied and compared with the steady-state operation, including ON-OFF and PEAK-BASE modulations of the liquid flow rate or concentrations, and a simultaneous modulation of both liquid flow rate and concentration. Attempts were also made to develop an unsteady-state operated trickle-bed reactor model based on a plug-flow model incorporating fluid flowing behavior, three-zone partial wetting catalyst, vapor-liquid phase equilibrium, and

enthalpy balance to predict the overall performance under unsteady-state operating conditions. Compared with the experimental observations, the model was generally reliable to predict performance enhancement for different modulation strategies.

GC/MS analysis of reactants and products during the hydrogenation of DCPD to THDCPD over nickel alloy catalyst SRNA-4 showed that the reaction is a consecutive process with two hydrogenated intermediates [237]. Density functional theory simulation confirmed that the double bond in the norbornene ring is easier to saturate than that in the cyclopentene ring, so the major intermediate is 8,9-dihydrodicyclopentadiene (8,9-DHDCPD). In comparison with Raney nickel, SRNA-4 had a significantly higher activity and allowed the reaction to proceed at lower temperature. The reaction conditions, including temperature and hydrogen pressure, were optimized. The optimal hydrogen pressure was 1.5 MPa. To avoid the decomposition of DCPD, a two-stage operation was designed: 373 K for 1 h and then 403 K for another 4 h. Under these conditions, the yield of THDCPD reached 98.5%. The apparent kinetics was calculated using the concentration-time data obtained during the experiments. The activation energy for DCPD to 8,9-DHDCPD and 8,9-DHDCPD to THDCPD reaction was 22.8 and 40.9 kJ/mol, respectively.

The kinetics of dicyclopentadiene hydrogenation were measured at different temperatures (323–353 K) under varying hydrogen pressure (0.5–1.5 MPa) with a range of Pd/C catalyst loading (0.25–1.00 mass-%) using ethanol as a solvent in a batch reactor [238]. The time-dependent concentration variations for each component were traced under the conditions of removing both the internal and external diffusion effects. A Langmuir-Hinshelwood mechanism was proposed with consideration of the non-competitive adsorption between the organic species with hydrogen, and the surface reaction was assumed to be the rate-determining step. The kinetic equations for the sequential reaction were derived on the basis of the analysis of mechanisms, and the model parameters were determined by fitting the experimental data in differential temperature using the method of Runge-Kutta. The reaction activation energies for the first and second steps were 3.19 and 31.69 kJ/mol, respectively, and the reliability of the model was verified by these experimental results in response to changed hydrogen pressure, reactant concentration, and catalyst loading.

A one-step, continuous-flow, catalytic hydrogenation-isomerization of DCPD directly to *exo*-THDCPD has been performed in a fixed-bed reactor [239]. This method is an environmentally friendly and more cost-effective single-step route than the use of  $\text{AlCl}_3$  and noble metals (palladium, platinum, and gold) and instead employs a combination of  $\text{Ni}/\gamma\text{-Al}_2\text{O}_3$  catalyst for hydrogenation and  $\text{Ni}/\text{H}\beta$  catalyst for isomerization. The bifunctional catalysts provided 100% DCPD conversion and 70% selectivity for *exo*-THDCPD and displayed a high stability without obvious deactivation during 200 h of testing. The influence of the operating conditions, including temperature, pressure, reaction time, reduction time, liquid hourly space velocity, nickel loading, catalyst weight ratio, calcination temperature of the catalysts, and type of solvent, was studied in detail.

A skeletal nickel catalyst supported on  $\text{Al}_2\text{O}_3$  achieved high dicyclopentadiene conversion (95%) and appropriate THDCPD selectivity (50%) during a 1000-h evaluation for dicyclopentadiene hydrogenation [240]. The optimum operating conditions were  $T = 393\text{K} = 120^\circ\text{C}$ ,  $P = 2.0\text{MPa}$ ,  $\text{LSHV} = 2.0\text{h}^{-1}$ , and hydrogen:oil ratio = 300:1.

The kinetic parameters that characterize the effect of the solvent nature, catalyst concentration, and temperature on the rate of hydrogen uptake in the hydrogenation process during the conversion of dicyclopentadiene (tricyclo[5.2.1.0<sup>2,6</sup>]decadiene-3,8) to dicyclopentene (tricyclo[5.2.1.0<sup>2,6</sup>]decene-3) in the liquid phase under mild conditions at atmospheric pressure over a finely divided 1% Pd/C catalyst have been measured [241]. To substantiate the theory of a stepwise sequence of saturation of the dicyclopentadiene double bonds in terms of the mechanism of heterogeneous catalysis, their reactivity was compared. It was shown that in the presence of a number of functionalized aromatic compounds as stabilizing additives, the yield of desired dicyclopentene increased to 98.5–99 mol-% with complete conversion of all dicyclopentadiene.

### 22.5.3 Oligomerization of Dicyclopentadiene

Cyclopentadiene dimer can be converted to higher-density oligomers by treatment with zeolites [242]. Oligomerization of dicyclopentadiene may be desirable for the synthesis of tricyclopentadiene or polymers, but it would result only in high-molecular-weight, viscous chemicals not suitable as liquid propellants. The synthesis of dicyclopentadiene is discussed in Section 24.1.

The processes of homo-oligomerization and co-oligomerization of dicyclopentadiene were investigated on the laboratory and pilot-plant scale under controlled isothermal or boiling conditions [243]. Reaction conditions and their effect on the quality of products were optimized. The oligomerization of dicyclopentadiene can proceed by two different mechanisms: **(1)** the Diels-Alder polyaddition at temperatures below 473 K (200 °C) and **(2)** thermal oligomerization at temperatures close to 533 K (260 °C). Products obtained by these two mechanisms differed significantly in their physical properties.

An investigation of the oligomerization of cyclopentadiene and its dimer, dicyclopentadiene, to tricyclopentadiene through Diels-Alder reaction at temperatures between 393 and 423 K (120 and 150 °C) showed that reaction temperature, pressure, and solvent influence the product yield [244]. At 423 K (150 °C), a yield of tricyclopentadiene up to 50% was obtained in the absence of solvents. The ratios of isomers in the product can be adjusted by using different solvents. The kinetics indicated that the rate was more sensitive to the concentration of cyclopentadiene than to that of dicyclopentadiene.

The oligomerization of *endo*-dicyclopentadiene in a continuous-flow reactor at elevated pressure was studied to produce tricyclopentadiene that was the precursor for the synthesis of high-energy-density fuels [245]. The composition of the products and

possible reaction pathways were analyzed, and the effects of reaction conditions were evaluated. Compared with the batchwise reaction at atmospheric pressure, the continuous-flow process could significantly enhance the reaction, increase the *exo/endo* ratio of tricyclopentadiene, and produce a new product *exo*-dicyclopentadiene. The *exo/endo* ratio was linearly dependent on the selectivity of *exo*-dicyclopentadiene. A high pressure above 1.2 MPa was necessary to facilitate the reaction. The conversion of *endo*-dicyclopentadiene increased with an increase of temperature, while the yield of tricyclopentadiene reached the highest value at 433 K (160 °C). However, the *exo/endo* ratio decreased with an increase of temperature. Increasing the pressure can improve the conversion, but the *exo/endo* ratio of tricyclopentadiene is unchanged. The conversion of dicyclopentadiene and the yield of tricyclopentadiene increased when the residence time was increased, but the reaction rate decreased. A short residence time was favorable because it led to a high *exo/endo* ratio for tricyclopentadiene. Under the optimal operating conditions, the conversion of *endo*-dicyclopentadiene was 82%, and the yield of tricyclopentadiene was 41%.

The effect of aluminum incorporation over KIT-6 on the catalytic performance in dicyclopentadiene oligomerization reaction has been investigated [246]. Al-KIT-6 was prepared by inserting alumina into KIT-6. The Al-KIT-6 prepared through aluminum grafting over KIT-6 was shown to have a well-arranged mesoporous structure, a large surface area, and a large pore size. Grafting of aluminum on KIT-6 generated Lewis acid sites with weak acid strength. The tricyclopentadiene yield over the Al-KIT-6 catalysts was higher than that over KIT-6 during dicyclopentadiene oligomerization and tricyclopentadiene isomerization. It might be attributed to the higher number of acid sites in the Al-KIT-6 catalyst. Higher *endo*-dicyclopentadiene conversion and higher tricyclopentadiene isomerization selectivity can be achieved by using Al-KIT-6 as compared with Al-MCM-41, likely due to the 3D mesopores and larger pore diameters of the KIT-6 aluminosilicates.

#### 22.5.4 Isomerization of Dicyclopentadiene

Isomerization of dicyclopentadiene is an important step in the production of JP-10. Accordingly, this reaction has been thoroughly investigated. *Endo*-dicyclopentadiene can be isomerized to the *exo*-isomer by thermal treatment at elevated temperature and pressure. The reaction temperature and pressure are key factors for this isomerization [247, 248].

The *endo*- to *exo*-isomerization of dicyclopentadiene can be performed in the liquid phase using acidic zeolites [249]. Among the several zeolites tested, the activity decreased in the sequence  $H\beta > HY > HUSY > HZSM-5 \approx H\text{-mordenite}$ . Beta and Y-type zeolites exhibited higher activity because of their large 3D channels. Surface passivation of  $H\beta$  confirmed that the reaction proceeds in the inner channels. Thermogravimetric measurements verified that HY is deactivated very quickly because the strong acidity induces serious coke formation, but this phenomenon was much less serious over

beta zeolites. Evaluation on H $\beta$  with different SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> ratios indicated that both the weak Lewis acid concentration and isomerization activity of zeolites monotonically decrease with the SiO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> ratio. Thus, a weak acid, especially a weak Lewis acid, of H $\beta$  favors the isomerization reaction. Calcination at 773 K (500 °C) provided the highest activity due to complete removal of template residues, generation of large amounts of weak Lewis acid, and good crystal structure. Zeolites deactivated due to coke deposition could be regenerated by calcination in air flow at 773 K (500 °C), and there was no obvious activity loss after they had been regenerated four times.

The isomerization of *endo*-dicyclopentadiene using aluminum-grafted MCM-41 zeolite was studied as an industrial practical synthesis route for *exo*-dicyclopentadiene [250]. The catalyst showed higher activity than microporous zeolites because its mesoporous structure gives free diffusion and excellent coke formation avoidance. A good correlation between the conversion of *endo*-dicyclopentadiene and the amount of Lewis acid was observed. Specifically, the weak Lewis acid sites catalyzed the *endo*-to-*exo*-isomerization. The moderate acidity sites accounted for the [2 + 2] cycloaddition of two dicyclopentadiene molecules. A catalyst with a Si/Al ratio of 8 was most active due to its highest concentration of weak Lewis acid sites. The addition of inert solvent, relatively low reaction temperature, and high catalyst dosage can improve the isomerization. The deactivated catalyst can be easily regenerated by calcination.

Mesoporous materials synthesized from commercial zeolite beta were applied to dicyclopentadiene oligomerization/dicyclopentadiene oligomer isomerization reactions [251]. A highly ordered mesoporous aluminosilicate, MMZ-H $\beta$ , was synthesized using commercially available zeolite beta as its framework. The MMZ-H $\beta$  catalyst showed high reaction activity and selectivity in dicyclopentadiene oligomerization/dicyclopentadiene oligomer isomerization reactions.

Isomerizing *endo*-dicyclopentadiene into the *exo*-isomer and some *exo*-tricyclopentadiene has great potential in synthesizing high-density fuels, but microporous acidic zeolites showed low activity due to the mass transfer limitation and shape selectivity. A modified HZSM-5 zeolite showed a higher *exo*-dicyclopentadiene yield than those of microporous H $\beta$  and mesoporous Al-MCM-41 [252]. In the oligomerization reaction, hierarchical HZSM-5 showed a higher tricyclopentadiene yield than that of H $\beta$ , and the yield was comparable to that obtained with Al-MCM-41.

MIL-100 (Fe, Cr) and MIL-101 (Fe, Cr) metal-organic frameworks have been used for the solvent-free isomerization of dicyclopentadiene from the *endo* to the *exo* form [253]. In the isomerization reaction, the conversion of *endo*-dicyclopentadiene and selectivity for the *exo*-dimer strongly depended on the nature of the active metal center. The MIL-100 (Fe) catalyst possessing more acid sites showed the highest catalytic activity among the metal-organic frameworks.

### 22.5.5 Thermal Decomposition of Dicyclopentadiene

When heated above 423 K (150 °C), dicyclopentadiene de-dimerizes in a reverse Diels-Alder reaction to yield cyclopentadiene. The reaction is reversible, and at room temperature cyclopentadiene slowly dimerizes to re-form dicyclopentadiene.

### 22.5.6 Hypergolic Ignition Reactions of Dicyclopentadiene

Dicyclopentadiene is produced as a by-product during the high-temperature steam cracking of petroleum gas oil. Dicyclopentadiene, methyldicyclopentadiene, and mixtures containing these fuels will ignite hypergolically with WFNA or RFNA [254, 255].

Solid dicyclopentadiene below its melting point has been evaluated as a binder in hybrid rocket fuel grains. The performance and the regression rate of this fuel can be increased by adding up to 25% sodium borohydride [256]. Similar improvements might be possible by suspending sodium borohydride in gelled liquid fuels containing dicyclopentadiene.

### 22.5.7 Fuel Mixtures with Dicyclopentadiene

*Endo*-dicyclopentadiene is a solid at room temperature, so it would have to be dissolved in a suitable solvent to make a liquid propellant fuel. Isobaric densities and viscosities of five binary liquid mixtures of *endo*-dicyclopentadiene with 2,2-dimethylbutane, 3-methylpentane, *n*-hexane, *n*-heptane, and 2,2,4-trimethylpentane were measured between 288 and 318 K at 5-K intervals [257]. Excess molar volume,  $V_{E_m}$ , viscosity deviation,  $\Delta\eta$ , and excess Gibbs energy of activation of viscous flow,  $G_E$ , have been calculated from these data.

## 23 *exo*-Tetrahydrodicyclopentadiene (JP-10)

*Exo*-tetrahydrodicyclopentadiene, also known as  $C_{10}H_{16}$ , tricyclo[5.2.1.0<sup>2,6</sup>]-decane, JP-10, CAS RN [2825-82-3], is a liquid with a favorable density (0.94 g/cm<sup>3</sup>) and a low freezing point of 194 K = -79 °C for a mixture of the three stereoisomers. *Exo*-tetrahydrodicyclopentadiene (*exo*-THDCPD) is the main ingredient of JP-10. The difference between pure *exo*-tetrahydrodicyclopentadiene (*exo*-THDCPD) and JP-10 is that the formulation meeting the military specification for JP-10 may contain additives to prevent corrosion and autoxidation.

*Exo*-tetrahydrodicyclopentadiene may also be known under one of the following names: tricyclo[5.2.1.0<sup>2,6</sup>]decane; 4,7-methano-1*H*-indene, octahydro-, (3 $\alpha$ ,4 $\beta$ ,7 $\beta$ ,7 $\alpha$ )-; 4,7-methanoindan, hexahydro-, *exo*-; *exo*-hexahydro-4,7-methanoindan; JP-10; *exo*-tetrahydrobicyclopentadiene; *exo*-tetrahydrodi(cyclopentadiene); *exo*-tricyclo(5.2.1.0<sup>2,6</sup>)decane; *exo*-trimethylenenorbornane; *exo*-5,6-trimethylenenorbornane; *exo*-octahydro-4,7-methano-1*H*-indene; *exo*-3,4,8,9-tetrahydrodicyclopent-

tadiene; endo-octahydro-4,7-methano-1*H*-indene; (3 $\alpha$ ,4 $\beta$ ,7 $\beta$ ,7 $\alpha$ )-octahydro-4,7-methano-1*H*-indene. The CAS RN for the endo stereoisomer is [2825-83-4].

### 23.1 Production of *exo*-Tetrahydrodicyclopentadiene

*Exo*-tetrahydrodicyclopentadiene is produced by hydrogenation of dicyclopentadiene, followed by isomerization. *Endo*-tetrahydrodicyclopentadiene is a solid at room temperature and has to be converted to its *exo*-tetrahydrodicyclopentadiene isomer to obtain a liquid fuel.

Several synthetic methods for making *exo*-tetrahydrodicyclopentadiene, including hydrogenation of dicyclopentadiene and isomerization from *endo*-tetrahydrodicyclopentadiene to *exo* form, have been summarized [258, 259]. Different hydrogenation catalysts and process were described, and several hydrogenation catalysts were compared. *Exo*-tetrahydrodicyclopentadiene can be made by continuous or intermittent batch processes, all of which involve isomerization catalysts. The mechanism of isomerization with Lewis acid catalysts has been explained. Additional work was aimed at improved hydrogenation catalysts and isomerization catalysts [149, 150, 259, 260].

An enantiomeric mixture of tricyclodecane can be obtained by hydrogenating dicyclopentadiene in an autoclave over a nickel/MgO/kieselguhr catalyst [261].

Hydrogenation of DCPD into *endo*-THDCPD in the presence of a Pd/Al<sub>2</sub>O<sub>3</sub> catalyst was experimentally and theoretically studied in a quasi-adiabatic trickle-bed reactor with a diameter of 24 mm and a length of 850 mm [235]. Effects of several operating parameters, including the liquid hourly space velocity (6–14 h<sup>-1</sup>), hydrogen pressure (1–2 MPa), inlet liquid concentration (0.5–1.3 mol/L), and inlet temperature (319–379 K) on the trickle-bed reactor performance were investigated systematically in terms of DCPD conversions, THDCPD yields, global hydrogenation rates, and axial temperature profiles. A plug-flow model for the trickle-bed reactor incorporating partial wetting, mass and enthalpy balance, and phase equilibria behavior was developed to simulate the experimental results, based on a phenomenological pellet-scale

model. A comparison of experimental and simulated results indicated that the developed model reliably predicted the performance and axial temperature profiles.

Hydrocarbon-soaked  $\text{AlCl}_3$  is a waste product that must be disposed of at the end of *exo*-tetrahydrodicyclopentadiene (*exo*-THDCPD) synthesis. H-type zeolites have been evaluated as a replacement for  $\text{AlCl}_3$  in *exo*-THDCPD production [262]. H-type Y zeolites with large pore size (0.74 nm) had sufficient activities for isomerization of *endo*-tetrahydrodicyclopentadiene (*endo*-THDCPD) to form *exo*-THDCPD. As for acidity strength, the moderate strength of zeolite acidity was favorable. The incorporation of fluorine generated more moderate acids, which improved the catalytic performance of zeolites to *endo*-to-*exo* yield of 92% and *exo* selectivity of 96% and suppressed the adamantane byproduct yield to 2.3%. When  $\text{NH}_4\text{F}/\text{SSY} = 6.57\%$ , calcined at 773 K (500 °C), was used, this showed a performance equivalent to  $\text{AlCl}_3$ .

Tetracyclo[74.0.0<sup>2,7</sup>.1<sup>3,6</sup>]tetradecane was synthesized from dicyclopentadiene and indene by a Diels-Alder reaction and hydrogenation [263]. Under the optimal conditions, the yield of tetracyclo[74.0.0<sup>2,7</sup>.1<sup>3,6</sup>]tetradecane was 68%. Properties of tetracyclo[74.0.0<sup>2,7</sup>.1<sup>3,6</sup>]tetradecane were measured. Density was 0.986 g/cm<sup>3</sup>, volumetric heat of combustion heat was 43.7 MJ/L, viscosity at 255 K (−18 °C) was 97.44 mm<sup>2</sup>s<sup>−1</sup>, flash point was 323 K (50 °C), and freezing point was 228 K (−45 °C). The thermal decomposition of tetracyclo[74.0.0<sup>2,7</sup>.1<sup>3,6</sup>]tetradecane was analyzed by a DSC. Results showed that tetracyclo[74.0.0<sup>2,7</sup>.1<sup>3,6</sup>]tetradecane has high thermal stability.

In a new process for continuous preparation of *exo*-THDCPD using a cascade of two reactors (a continuous-flow bubbling hydrogenation reactor and a continuous-flow isomerization tank reactor), DCPD was hydrogenated to *endo*-THDCPD over a Pd/C catalyst, and the *endo*-THDCPD was isomerized to *exo*-THDCPD over an  $\text{AlCl}_3$  catalyst [264]. Results showed that the optimum liquid-phase continuous-flow process conditions of preparing *exo*-THDCPD were mass hourly space velocity of 2.4 h<sup>−1</sup>, hydrogenation pressure of 0.1 MPa,  $\text{H}_2$  gas flow rate of 80 mL/min, DCPD concentration of 0.76 mol/L, hydrogenation reaction temperature of 303 K (30 °C), and isomerization reaction temperature of 343 K (70 °C), with an *exo*-THDCPD yield of 92.5%.

It is very difficult to separate *endo*- and *exo*-tetrahydrodicyclopentadiene by distillation because the vapor pressures are so similar. The minimum reflux ratio and minimum number of stages were calculated to obtain products having at least a quality of 99.0 mass-% of each component [265]. Separation by distillation would require a tall, fractionated distillation column with 60 theoretical plates operating at a high reflux ratio. The theoretical number of stages was estimated from the correlation of number of stages and reflux ratio.

### 23.1.1 Catalysts for Preparation of *exo*-Tetrahydrodicyclopentadiene by Hydrogenation

THDCPD can be produced through fixed-bed catalytic hydrogenation of DCPD [266]. The effects of catalyst composition and surface pretreatment methods of  $\gamma$ - $\text{Al}_2\text{O}_3$  support on reaction activity were investigated. An impregnated single-ingredient nickel catalyst suitable for this catalytic hydrogenation system with an active metal load of 15% Ni and a support that was physically and chemically pretreated  $\gamma$ - $\text{Al}_2\text{O}_3$  was tested. The activation conditions and the optimum activation process were determined, which were as follows: 423–433 K (150–160 °C),  $P_{\text{H}_2}$ : 1 MPa, space velocity 20–30  $\text{h}^{-1}$ ,  $\text{H}_2/\text{DCPD}$  (mole ratio) 3:1. Under these conditions, the conversion of DCPD was better than 98%, and the yield of THDCPD was close to 95%.

The synthesis of THDCPD from DCPD by catalytic hydrogenation has been studied using a Ziegler-Natta homogeneous catalyst [267]. The results showed that the catalyst had good activity and selectivity; the amount of nickel in the homogeneous catalyst was only 1% that of the heterogeneous catalyst.

Liquid-phase hydrogenation of DCPD to form *endo*-THDCPD was investigated by using SRNA-4 amorphous catalyst under different reaction conditions, including agitation speed, reaction temperature, pressure, and the amount of catalyst used [268]. It was found that the hydrogenation of the DCPD intermediate is a consecutive reaction, during which 9,10-dihydrodicyclopentadiene (9,10-DHDCPD) is a main intermediate and 1,2-dihydrodicyclopentadiene (1,2-DHDCPD) is a minor one. The hydrogenation of DCPD to form 9,10-DHDCPD could be conducted under a mild condition, but more severe conditions are needed for hydrogenating 9,10-DHDCPD to form *endo*-THDCPD. The hydrogenation of DCPD to form *endo*-THDCPD should be carried out in two steps. A temperature of 383 K (110 °C) is used for the first step, and 403 K (130 °C) is used for the second step. A pressure of 1.5 MPa and catalyst amount of 1.18 mass-% were used for both steps. The SRNA-4 amorphous catalyst exhibited hydrogenation activity superior to that of Raney nickel catalyst. When the SRNA-4 amorphous catalyst was used, the intermediate 1,2-DHDCPD could be produced during hydrogenation of DCPD, the reaction temperature and pressure could be lower, the catalyst amount used and reaction time could be less, and the number of by-products could also be fewer than when a Raney nickel catalyst is used.

Hydroconversion of DCPD into tetrahydrodicyclopentadiene has been carried out with a single-step route over a supported gold catalyst [269]. The physicochemical properties of the catalysts were studied using X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM),  $\text{N}_2$ -adsorption, and  $\text{NH}_3$ -temperature-programmed desorption (TPD). The influence of reaction conditions such as temperature, pressure, and reaction duration were studied in detail. The studies revealed that pressure and temperature play crucial roles in the reaction. Moderate acid sites in the catalysts are chiefly involved in isomerization, and gold catalyzes hydrogenation of the intermediates. Analysis of the product stream at different intervals

indicated a dissociation-recombination mechanism for the reaction. Reusability of the catalyst was demonstrated by conducting five runs with the same catalyst. Even after the fifth run, the catalyst retained relatively high conversion and selectivity to *exo*-THDCPD.

A one-step, continuous flow phase, catalytic combined hydrogenation-isomerization of DCPD directly into *exo*-THDCPD was carried out in a fixed-bed reactor [239]. This method is an environmentally friendly and more cost-effective single-step route than the use of  $\text{AlCl}_3$  or noble metals (palladium, platinum, and gold) and instead employs a combination of  $\text{Ni}/\gamma\text{-Al}_2\text{O}_3$  for hydrogenation and  $\text{Ni}/\text{H}\beta\text{-zeolite}$  for isomerization. The bifunctional catalysts provided 100% DCPD conversion and 70% selectivity for *exo*-THDCPD and displayed a high stability without obvious deactivation over 200 h of testing. The synergistic effect of nickel hydrogenation activity and the isomerization activity of the supports is a key factor for the catalytic combined hydrogenation-isomerization of DCPD. The reaction operating conditions, including temperature, pressure, reaction time, reduction time, liquid hourly space velocity, nickel loading, catalyst weight ratio, calcination temperature of the catalysts, and type of solvents, were optimized.

There are several chemical methods for the synthesis of *exo*-THDCPD. However, it is still a challenge to synthesize *exo*-THDCPD economically. *Exo*-THDCPD has successfully synthesized from DCPD through a simple and environmentally compatible single-step hydroconversion reaction over a mesoporous supported nickel nanocatalyst ( $\text{Ni}/\text{MCM-41}$ ) [270]. The reaction was carried out in an autoclave under a hydrogen pressure ranging from 2.07 to 2.76 MPa (300–400 psia) and temperature ranging from 403 to 423 K (130–150 °C). Progress was monitored by gas chromatography, which revealed that the reaction mechanism goes through dissociation-recombination of DCPD. The major reaction parameters such as temperature, pressure, and nanocatalyst have been experimentally examined for the best yield (85%) of the product. A structural analysis of freshly produced *exo*-THDCPD was carried out using  $^1\text{H}$  NMR and FTIR, and the physicochemical properties were evaluated and confirmed. Good-quality nanocatalyst  $\text{Ni}/\text{MCM-41}$  has been synthesized by the impregnation incipient wetness method and characterized using XRD, energy-dispersive X-ray analysis (EDAX), TEM, and Brunauer-Emmett-Teller (BET) techniques. The nanocatalyst is highly reactive due to its mesoporous structure having appropriate size and shape, which gives free diffusion of the molecules. Repeatability of the nanocatalyst showed good reactivity up to four consecutive runs.

### 23.1.2 Isomerization of Tetrahydrodicyclopentadiene

The isomerization of freshly hydrogenated dicyclopentadiene is part of the production process, and there is some overlap between the following and the previous sections when it comes to the selection of catalysts for hydrogenation and isomerization.

### 23.1.2.1 Aluminum Chloride Catalysts for Isomerization of Tetrahydrodicyclopentadiene

For a very long time, aluminum chloride,  $\text{AlCl}_3$ , was the preferred catalyst for isomerization of *endo*-tetrahydrodicyclopentadiene (*endo*-THDCPD) [271, 272], along with an aluminum halide hydrate as a cocatalyst [273]. The resulting product has a density of  $0.936 \text{ g/cm}^3$  and a heat of combustion of  $39.4 \text{ MJ/L}$  ( $149 \text{ MJ/gal} = 141720 \text{ BTU/gal}$ ).

For the isomerization of *endo*-THDCPD, anhydrous  $\text{AlCl}_3$  was used as catalyst [274]. The effects of catalyst amount, reaction temperature on reaction rate, conversion, yield, selectivity, and by-product formation were investigated. Optimal reaction conditions were catalyst 3%, temperature  $353 \text{ K}$  ( $80^\circ\text{C}$ ), and reaction time 100 min, with conversion of 94.67%, yield 92.26%, and selectivity 97.36%.

Aluminum chloride was again used as a catalyst, but with different solvents for the isomerization of *endo*-THDCPD to *exo*-THDCPD [275]. The effect of the solvents on reaction rate, conversion, yield, selectivity, and by-products was investigated. The results showed that different solvents have different effects on the isomerization. Reaction conversion and yield decreased greatly with toluene as the only solvent. Compared with the isomerization without solvent, using 1,2-dichloroethane as solvent had the best effect on the isomerization under the optimal reaction conditions of a temperature of  $333 \text{ K}$  ( $60^\circ\text{C}$ ) and 3 mass-% catalyst. Less adamantane and no tar were found in the product. The reaction results were conversion 97%, yield 97%, and selectivity 99.9%. A kinetic equation for *endo*-THDCPD isomerization was derived from the measured conversion rates.

Modified clays were pretreated with a pyridine hydrochloride/ $\text{AlCl}_3$  mixture and used for supporting a chloroaluminate ionic liquid catalyst for the isomerization of *endo*-tetrahydrodicyclopentadiene into the corresponding *exo*-isomer [276]. Nearly quantitative conversion to the desired product and nearly quantitative selectivity were achieved by isomerization of *endo*-tetrahydrodicyclopentadiene into the corresponding *exo*-isomer using clay-supported ionic liquid catalysts.

The effects of solvents, catalyst loadings, solvent amount, and reaction time during the preparation of *exo*-tetrahydrodicyclopentadiene by isomerization of *endo*-tetrahydrodicyclopentadiene over  $\text{AlCl}_3$  catalyst were investigated [277]. The optimum operating conditions were obtained as follows:  $(\text{CH}_2\text{Cl}_2):(\text{endo-tetrahydrodicyclopentadiene})$  ratio = 0.8, catalyst loading = 20%, and reaction time = 3 h. Conversion of 97% and selectivity of 99% were attained under these optimum conditions.

### 23.1.2.2 Zeolite Catalysts for Isomerization of Tetrahydrodicyclopentadiene

The *endo*- to *exo*-isomerization of tetrahydrodicyclopentadiene can be catalyzed by commercially available zeolites [278]. Several zeolites were tested, and the influences of calcination temperatures, Si/Al ratio, and cations of the zeolites on the reaction were investigated. The results showed that, because of their large pore size and relative strong acidity, HY zeolites were more active than other zeolites and Y zeolites

with other cations. In all HY zeolites with different Si/Al ratios, H-USY was the best choice. On one hand, H-USY has more moderate acid sites than others. On the other hand, the high thermal stability of H-USY makes it a suitable choice for recycling catalysts. In all the zeolites tested, H-USY calcined at 723 K (450 °C) was the most favorable catalyst. Regeneration of H-USY showed no decrease of *exo*-yield, while it had better *exo*-selectivity.

Aluminum chloride, which is generally used as catalyst for the isomerization of *endo*-THDCPD, is considered environmentally unsafe to dispose of in landfills. Instead, zeolites were used as catalysts to develop an environmentally more friendly process for the production of *exo*-THDCPD [279]. Among the several zeolites tested, Y type zeolites with larger pores were the most active. HUSY zeolite was more efficient than HSSY due to the abundance of weak acidic sites. Loading of fluorine could suppress the medium acid and increase the weak acid, promoting the selectivity to *exo*-THDCPD. The optimal reaction conditions were as follows: 6.6% F/HSSY as catalyst, temperature 468 K (195 °C), and catalyst percentage 20%. In this case, the conversion of *endo*-THDCPD was 94%, and the selectivity to *exo*-THDCPD was 98.4%. The deactivated catalyst could be effectively regenerated by calcination at 823 K (550 °C).

Vapor-phase isomerization of *endo*-THDCPD to *exo*-THDCPD over zeolite catalysts (HY, H-USY, H $\beta$ , HZSM-5, and HMOR) was studied as an environmentally more friendly synthesis route for *exo*-THDCPD [280]. The HY and H-USY catalysts showed catalytic activity, whereas the H $\beta$ , HZSM-5, and HMOR catalysts did not. Higher yield of *exo*-THDCPD was obtained over the H-USY catalyst than over the HY catalyst, which was attributed to the presence of strong acid sites and mesopores in the H-USY catalyst. The yield of *exo*-THDCPD obtained via vapor-phase isomerization was better than that reported via liquid-phase isomerization. Under the optimized conditions, high-purity (98 mass-%) *exo*-THDCPD was directly obtained without any separation processes. Although some deactivation of the catalyst with time on-stream was observed, the activity could be recovered easily via regeneration in air.

The synthesis of *exo*-THDCPD through the isomerization of *endo*-THDCPD was investigated over HY zeolite catalysts [281]. Conversion of *endo*-THDCPD increased with an increase of the Si/Al<sub>2</sub> ratio of HY zeolite catalysts, which was attributed to an increase of acid strength with increasing Si/Al<sub>2</sub> ratio. The yield of *exo*-THDCPD, however, was

highest over an HY catalyst with an Si/Al<sub>2</sub> ratio of 30 because the production of cyclopentadiene and oligomers was minimized. The optimal reaction temperature was 453 K (180 °C) because the higher reaction temperature increased the production of unwanted by-products. The yield of *exo*-THDCPD also increased with the amount of catalyst in the feed. In the isomerization reaction of *endo*-THDCPD using the HY zeolite catalysts, it was confirmed that the internal diffusion resistance in the pore of catalysts would have more significant effects on the reaction activity than that of the external diffusion resistance of catalysts.

### 23.1.2.3 Other Catalysts for Isomerization of Tetrahydrodicyclopentadiene

The isomerization of *endo*-THDCPD to *exo*-THDCPD (JP-10) and adamantane was investigated using ionic liquids as acid catalysts to explore a less contaminating alternative to the widely used AlCl<sub>3</sub> [282]. Ionic liquids composed of various 1-alkyl-3-methylimidazolium chlorides ([Rmim]Cl) and metal chlorides were tested, and [Bmim]Cl/AlCl<sub>3</sub> was the best candidate. The effects of acidity and dosage of ionic liquids, reaction temperature, and time were studied for *endo*- to *exo*-isomerization of THDCPD. The reaction occurred quickly under mild conditions, with both conversion and selectivity beyond 98%. Purifying the reactant could suppress deactivation of ionic liquids, and the used ionic liquids could be recycled four times by heating under vacuum after each run. By adjusting the reaction conditions to more severe conditions, i.e., higher ionic liquid dosage, higher temperature, and longer time, *exo*-THDCPD was further isomerized to adamantane. The highest yield of adamantane was only 50.9% [283].

*Endo*-THDCPD can be isomerized to its *exo*-isomer (JP-10) by using chloroaluminate ionic liquids as catalysts [284]. The catalyst activity and selectivity could be optimized by varying the mole fraction of AlCl<sub>3</sub> in the ionic liquid. The formation of undesirable by-products derived from side reactions such as skeletal rearrangement, alkylation, cracking, and dimerization could be minimized by appropriate catalyst design and adjustment of the reaction conditions. The catalyst system was further optimized by selecting 1-butyl-3-methylimidazolium chloride as the basic ionic liquid and adding 0.60–0.65 mole fraction of AlCl<sub>3</sub> as the promoter. Using the optimized catalyst system, the isomerization of *endo*-THDCPD to *exo*-THDCPD proceeded at a fast rate at 323 K (50 °C), with 98.9% conversion and 100% selectivity. The catalyst longevity was demonstrated by recycling the ionic liquid several times without a noticeable reduction in catalytic activity.

A palladium or nickel compound, PdCl<sub>2</sub>, Pd(acac)<sub>2</sub>, or Ni(acac)<sub>2</sub>, can be used as a catalyst for the catalytic isomerization of *endo*-tetrahydrodicyclopentadiene to *exo*-tetrahydrodicyclopentadiene [285].

A series of heterogeneous catalysts for the isomerization of *endo*-THDCPD to its *exo*-isomer (*exo*-THDCPD) based on different metal chlorides (AlCl<sub>3</sub>, NbCl<sub>5</sub>, ZnCl<sub>2</sub>) immobilized on silica gel were investigated [286]. The physicochemical properties of the catalysts were studied using SEM, low-temperature nitrogen adsorption, and NH<sub>3</sub>-

TPD. Supported  $\text{AlCl}_3$  exhibited the best catalyst activity and a high selectivity without side reactions such as skeletal rearrangement or alkylation, whereas  $\text{NbCl}_5$  and  $\text{ZnCl}_2$  immobilized on  $\text{SiO}_2$  showed much less catalytic activity.

## 23.2 Physical Properties of *exo*-Tetrahydrodicyclopentadiene

This section overlaps with a similar section, Section 7.2 of chapter “Jet Fuels” in *Encyclopedia of Liquid Fuels*, on the physical properties of JP-10. The main ingredient of JP-10 is *exo*-tetrahydrodicyclopentadiene, and thus the physical properties of JP-10 and the pure *exo*-tetrahydrodicyclopentadiene compound are very similar. The difference between the two is that JP-10 may contain some additives, which would change the physical properties of pure *exo*-tetrahydrodicyclopentadiene. If no better data are available, they could be substituted for each other. If a reader is looking for *exo*-tetrahydrodicyclopentadiene physical property data in this section and does not find them, it would be advisable to go back to the JP-10 section and start looking there.

Physical properties of tetrahydrodicyclopentadiene are summarized in Table 28 and discussed in more detail in individual sections following the table. A separate table, Table 31, summarizes the thermodynamic properties of tetrahydrodicyclopentadiene. A summary of physical properties of *exo*-tetrahydrodicyclopentadiene is available online at [287].

**Table 28:** Physical properties of tetrahydrodicyclopentadiene.

| Property                                 | SI units                              | Other units   | References |
|------------------------------------------|---------------------------------------|---------------|------------|
| Molecular mass                           | 136.2340 g/mol                        | 7.3403 mol/kg |            |
| Freezing point, <i>endo</i>              |                                       |               | [17]       |
| Freezing point, <i>exo</i>               | 183.2 K                               | −89.9 °C      |            |

| Critical temperature, <i>exo</i>         | 633.90 K                              | 360.8 °C      | [265]      |
| Critical temperature, <i>endo</i>        | 639.90 K                              | 366.8 °C      |            |

### 23.2.1 Freezing Point of *exo*-Tetrahydrodicyclopentadiene

The freezing point of *exo*-tetrahydrodicyclopentadiene is 183.2 K (−89.9 °C). Other sources list a freezing point of 182.4 K (−90.7 °C) [223].

### 23.2.2 Boiling Point of *exo*-Tetrahydrodicyclopentadiene

In an effort to separate *endo*- and *exo*-tetrahydrodicyclopentadiene by distillation, the boiling points of the two stereoisomers were determined [265]: 459.38 K for *exo*-tetrahydrodicyclopentadiene and 463.60 K for *endo*-tetrahydrodicyclopentadiene.

### 23.2.3 Density of *exo*-Tetrahydrodicyclopentadiene

The density of JP-10 per MIL-DTL-87107E is 0.934–0.943 g/cm<sup>3</sup> at 288 K (15 °C). The density of *exo*-tetrahydrodicyclopentadiene (JP-10) in the temperature range 219–323 K (−54 to +50 °C) can be expressed by a linear equation [222]

$$\rho = \rho_0 - Bt$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $t$  is the temperature in °C. The constants  $\rho_0$  and  $B$  are listed in Table 25 (in the section on perhydrodininorbornadiene). A similar equation for the range 203 to 348 K (−70 to +75 °C) was given in an earlier report [227]:

$$\rho = \rho_0 - bt = 0.950 - 7.7 \times 10^{-4}t$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $t$  is the temperature in °C. A similar equation uses a Fahrenheit temperature scale

$$\rho = 0.96407 - 0.0004391t$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $t$  is the temperature in °F [72].

The density and velocity of sound measurements with JP-10 are summarized in *Encyclopedia of Liquid Fuels* in the chapter “Jet Fuels,” Sections 7.2.2 and 7.2.4 [289].

### 23.2.4 Vapor Pressure of *exo*-Tetrahydrodicyclopentadiene

The vapor pressure of liquid *exo*-tetrahydrodicyclopentadiene (tricyclo[5.2.1.0<sup>2,6</sup>]-decane) in the temperature range 358–417 K can be calculated from the equation

$$\log P = (-2273.7/T) + 7.782$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin [2]. The enthalpy of formation is  $-60.17 \pm 3.8$  kJ/mol ( $-14.38 \pm 0.90$  kcal/mol).

The vapor pressures of *endo*- and *exo*-tetrahydrodicyclopentadiene were measured over the range 335 to 460 K and can be expressed by the Antoine equation [288]

$$\ln P = A - [B/(T + C)]$$

where  $P$  is the vapor pressure in kPa and  $T$  is the temperature in kelvin. The constants A, B, and C are listed in Table 29.

**Table 29:** Antoine constants and standard deviations for the fitted vapor pressures of *exo*-THDCPD and *endo*-THDCPD.

| Component           | A        | B        | C      | Standard deviations |
|---------------------|----------|----------|--------|---------------------|
| <i>Exo</i> -THDCPD  | 17.01851 | 6339.506 | 52.047 | 0.00081             |
| <i>Endo</i> -THDCPD | 16.84102 | 5992.073 | 26.870 | 0.00075             |

Data source: [288]

The vapor pressure of *exo*-tetrahydrodicyclopentadiene is shown in Figure 30, where the solid circles are measured data points and the solid line is the result of the Antoine equation. A similar chart is available for *endo*-tetrahydrodicyclopentadiene. As can be seen from Figure 31, the vapor pressure of *exo*-tetrahydrodicyclopentadiene is slightly higher than that of the *endo*-conformer.

**Figure 30:** Vapor pressure of *exo*-tetrahydrodicyclopentadiene. (Reprinted and modified from [288], with permission from ©2006 Elsevier; permission conveyed through RightsLink.)

**Figure 31:** Comparison of vapor pressures of *exo*- and *endo*-tetrahydrodicyclopentadiene. (Image created by Schmidt 2020 based on data from [288].)

**23.2.5 Viscosity of *exo*-Tetrahydrodicyclopentadiene**

The kinematic viscosity of JP-10 is 40 mm<sup>2</sup>/s = 40 cSt at 219 K (−54 °C) and 10 mm<sup>2</sup>/s = 10 cSt at 255 K (−18 °C). The viscosity of *exo*-tetrahydrodicyclopentadiene (JP-10) in the temperature range 219–323 K (−54 to +50 °C) can be expressed by the following equation [223]:

$$\ln \eta = A + B/(T - T_0)$$

where  $\eta$  is the viscosity in Poise and  $T$  is the temperature in kelvin.  $A$ ,  $B$ , and  $T_0$  are constants listed in Table 26 (in the section on perhydrodinorbornadiene). Additional density and viscosity data are available in [223] for mixtures of *exo*-THDCPD with the isomers of PHDNBD.

The viscosity of *exo*-tetrahydrodicyclopentadiene at 233 K (−40 °C) is 17 cPs [290]. The density of this sample was 0.9369 g/cm<sup>3</sup> at 293 K. The viscosity and density of *exo*-THDCPD was measured between 239 and 341 K (−30 and +155 °F) as listed in Table 30.

**Table 30:** Kinematic viscosity and density of *exo*-tetrahydrodicyclopentadiene.

| Temperature                |        |        |        |
|----------------------------|--------|--------|--------|
| −30                        | 32     | 77     | 155 °F |
| −34                        | 0      | 25     | 68 °C  |
| 239                        | 273    | 298    | 341 K  |
| Viscosity, cSt             |        |        |        |

Data source: [72]

### 23.2.6 Surface Tension of *exo*-Tetrahydrodicyclopentadiene

The surface tension of *exo*-tetrahydrodicyclopentadiene is 37.850, 35.928, 32.926, 30.534, and 26.097 dyn/cm at 219, 239, 273, 295, and 343 K (−65, −30, +32, +72, and +158 °F), respectively [72].

### 23.2.7 Thermodynamic Properties of *exo*-Tetrahydrodicyclopentadiene

Thermodynamic properties of *exo*-tetrahydrodicyclopentadiene are listed in Table 31. For some of the literature sources, it was not clear whether the experiments had been done with the *exo* or *endo* conformer or a mixture of the two. Most likely the data reported for the solid state were for the *endo* conformer.

**Table 31:** Thermodynamic properties of *exo*-tetrahydrodicyclopentadiene.

| Property                                                                | SI units                                   | Other units                                  | References |

#### 23.2.7.1 Heat Capacity of *exo*-Tetrahydrodicyclopentadiene

The heat capacity of liquid *exo*-THDCPD in the range 210 to 340 K can be calculated from

$$c_p = 0.254 + 0.00088 (T - 182.4)$$

where  $c_p$  is the heat capacity in cal g<sup>−1</sup> °C<sup>−1</sup> and  $T$  is the temperature in kelvin [227]. The heat capacity of JP-10 in the range 260 to 465 K can be calculated from the equation

$$c_p = 0.10423 + 0.76872 \times 10^{-3} T + 0.46992 \times 10^{-6} T^2$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin [224]. This equation gives a heat capacity of  $213.87 \text{ J mol}^{-1} \text{ K}^{-1}$  at 298 K. Other sources gave heat capacities of  $236.6 \text{ J mol}^{-1} \text{ K}^{-1}$  at 298.15 K ( $0.415 \text{ cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  at  $25 \text{ } ^\circ\text{C}$ ) [77].

Another equation for the heat capacity of JP-10 in the range 275 to 365 K was listed as

$$c_p = 0.046061 + 0.0012371 T$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin [293, 294]. This equation gives a heat capacity of  $236.5 \text{ J mol}^{-1} \text{ K}^{-1}$  at 298 K.

The heat capacity of *exo*-THDCPD at 233, 293, and 339 K ( $-40$ ,  $+20$ , and  $+66 \text{ } ^\circ\text{C}$ ) is 1.335, 1.573, and  $1.791 \text{ J g}^{-1} \text{ K}^{-1}$  ( $0.319 \text{ cal}$ ,  $0.376$ , and  $0.428 \text{ cal g}^{-1} \text{ } ^\circ\text{C}^{-1}$ ), respectively (average of two consecutive tests [72]).

The isobaric molar heat capacity of *exo*-THDCPD was measured at temperatures from 323 to 523 K with an interval of 10 or 20 K and at pressures from 0.1 to 6.0 MPa with an interval of about 1 MPa by using a flow calorimeter [295]. The results showed that the isobaric heat capacities of *exo*-THDCPD increased gradually with increasing temperature at fixed pressure and decreased with increasing pressure at fixed temperature. A polynomial equation was derived that expresses the heat capacity as a function of both temperature and pressure:

$$C_p = a_1 + a_2 T + a_3 T^2 + a_4 T^3 + a_5 T^4 + a_6 \ln p + a_7 \ln p^2$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{ K}^{-1}$ ,  $T$  is the temperature in kelvin, and  $p$  is the pressure in MPa;  $a_1$  through  $a_7$  are the constants listed in Table 32.

**Table 32:** Parameters of the correlation equation for the heat capacity of *exo*-THDCPD at pressures from 0.1 to 6 MPa and at temperatures from 323 to 523 K.

| Parameter | Value                       | Units                                               |
|-----------|-----------------------------|-----------------------------------------------------|
| $a_1$     | -4112.1053                  | $\text{J K}^{-1} \text{ mol}^{-1}$                  |
| $a_2$     | 41.466491                   | $\text{J K}^{-2} \text{ mol}^{-1}$                  |
| $a_3$     | -0.14878625                 | $\text{J K}^{-3} \text{ mol}^{-1}$                  |
| $a_4$     | $2.3636990 \times 10^{-4}$  | $\text{J K}^{-4} \text{ mol}^{-1}$                  |
| $a_5$     | $-1.3821147 \times 10^{-7}$ | $\text{J K}^{-5} \text{ mol}^{-1}$                  |
| $a_6$     | -1.1282113                  | $\text{J K}^{-1} \text{ mol}^{-1} \text{ MPa}^{-1}$ |
| $a_7$     | -0.58042910                 | $\text{J K}^{-1} \text{ mol}^{-1} \text{ MPa}^{-2}$ |

Data source: [295]

Figure 32 shows a comparison of measured and extrapolated isobaric heat capacity data in the Zhang, Liu, and He 2017 [295] work and reported data in literature. The extrapolated data agreed well with the earlier data reported by Chickos et al. 2002 [292] and Monihan et al. 1978 [226], but the measured data were about 18% below the data reported by Steele et al. 1989 [125].

**Figure 32:** Measured, extrapolated, and reported heat capacity data of *exo*-THDCPD at 0.1 MPa. (Reprinted and modified from [295], with permission from ©2017 Elsevier; permission conveyed through RightsLink.)

### 23.2.7.2 Enthalpy of Formation of *exo*-Tetrahydrodicyclopentadiene

The enthalpy of formation of *exo*-tetrahydrodicyclopentadiene vapor is  $-60.17 \pm 3.8$  kJ/mol ( $-14.38 \pm 0.90$  kcal/mol) [2]. The heat of combustion of crystalline *exo*-(*endo*-?) tetrahydrodicyclopentadiene is  $6109 \pm 3$  kJ/mol ( $1460.04 \pm 0.60$  kcal/mol). This source does not provide a number for this fuel in the liquid state.

Thermodynamic parameters for the parent *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane molecule and of all the tricyclodecyl radicals corresponding to the loss of hydrogen atoms from different carbon sites were determined using several density functional theory (DFT) and composite computational chemistry methods [296]. Five isodesmic reactions, three involving bridged hydrocarbon reference molecules with similar ring strains, were employed to produce a cancelation of systematic calculation errors in evaluation of standard, gas-phase formation enthalpies at 298 K. The enthalpy of formation  $\Delta H_f^{o298}$  for *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane was predicted to be  $-81.6 \pm 5.4$  kJ/mol ( $-19.5 \pm 1.3$  kcal/mol), which is several kcal/mol lower than the commonly used values. Results from the use of five different DFT methods were in very good agreement with composite level values for all reactions used for the radicals. The *exo* and *endo* isomers of *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane were both determined to have chair and boat conformers.

Combining calculated values for the gas-phase heat of formation with recent measurements of the heat of vaporization yielded recommended values for  $\Delta H_f^\circ(298)_{\text{liq}}$  of  $-126.4$  and  $-114.7$  kJ/mol for the *exo* and *endo* isomers, respectively [297].

The efficiency of DFT was investigated for estimating the gas-phase and condensed-phase heats of formation of 27 polycyclic saturated hydrocarbons  $C_nH_n$  ( $5 \leq n \leq 12$ ) [298]. The homodesmotic reactions

were used where the experimental reference data are available in the literature. The reliability of predicted results through these density functionals was also compared with the corresponding values calculated by other computational approaches. All three methods showed excellent linear relationships with the experimental data.

Based on the reported heat of combustion of liquid XTHDCPD of  $10682.01 \pm 0.90$  cal/g =  $1457.68 \pm 0.33$  kcal/mol, the enthalpy of formation was assumed to be  $-122.8 \pm 1.5$  kJ/mol ( $-29.35 \pm 0.35$  kcal/mol) [291].

### 23.2.7.3 Enthalpy of Fusion of *exo*-Tetrahydrodicyclopentadiene

The molar heat of fusion of *exo*-tetrahydrodicyclopentadiene (XTHDCPD,  $C_{10}H_{16}$ ,  $M = 136.2$  g/mol) at 182.4 K is 1.1 kJ/mol [227]. Later measurements gave similar data: 1.2 kJ/mol at 183.2 K [292]. Low-temperature DSC studies of both isomers revealed solid-to-solid phase transitions. The *endo* isomer, which is a plastic at room temperature, exhibited a solid-to-solid phase transition at  $T = 214$  K with  $\Delta H = 10.7 \pm 0.13$  kJ/mol and a melting temperature of 356.8 K with some evidence of polymorphism. The *exo* isomer exhibited a solid-phase transition at  $T = 162.1$  K with  $\Delta H = 3.18 \pm 0.11$  kJ/mol and a melting temperature of 183.2 K. The more recent data do not quite match older heat of fusion data measured at 352 K with  $2.95 \pm 0.04$  kJ/mol ( $0.705 \pm 0.01$  kcal/mol) [2].

### 23.2.7.4 Enthalpy of Vaporization and Sublimation of *exo*-Tetrahydrodicyclopentadiene

The vaporization enthalpies ( $\Delta H_m$  (298.15 K) of *endo*- and *exo*- tetrahydrodicyclopentadiene THDCPD) have been measured by correlation gas chromatography [292]. Values of  $\Delta H = (50.2 \pm 2.3)$  kJ/mol and  $\Delta H = (49.1 \pm 2.3)$  kJ/mol were obtained for the *endo*- and *exo*-configurations, respectively. The sublimation enthalpy of the *endo* isomer is  $\Delta H = 51.2 \pm 2.4$  kJ/mol and was obtained by combining fusion and vaporization enthalpies adjusted as necessary to  $T = 298.15$  K. Enthalpies of vaporization and sublimation were combined with the respective enthalpies of formation previously reported to yield gas-phase values for *endo*-THDCPD and *exo*-THDCPD of  $\Delta H = -61.9 \pm 3.2$  kJ/mol and  $\Delta H = -73.7 \pm 2.7$  kJ/mol, respectively. Based on vapor-pressure measurements in the range 359 to 443 K, the heat of sublimation at 298 K was calculated to be  $52.96 \pm 1.3$  kJ/mol at 298 K [139].

Older sources reported an enthalpy of vaporization of the liquid of  $53.4 \pm 0.8$  kJ/mol ( $10.40 \pm 0.2$  kcal/mol), calculated from vapor pressure measurements in the range 359 to 443 K [2].

### 23.2.7.5 Heat of Combustion of *exo*-Tetrahydrodicyclopentadiene

It is inconvenient that the heat of combustion and the enthalpy of formation of *exo*-tetrahydrodicyclopentadiene reported in [2] contain data only for the solid and vapor states but not for the liquid state at 298 K. Heat of combustion of JP-10, which would not be very different from that of pure tetrahydrodicyclopentadiene, is reported in this volume in chapter “Jet Fuels.”

The net (lower) heat of combustion of JP-10 per ASTM D240 or D4809 is 42.1 MJ/kg. The heat of combustion of *exo*-tetrahydrodicyclopentadiene is  $6099 \pm 1$  kJ/mol ( $1457.74 \pm 0.26$  kcal/mol) [77]. An earlier report gave the heat of combustion of *exo*-THCPD as  $10682.01 \pm 0.90$  cal/g =  $1457.68 \pm 0.33$  kcal/mol [291]. The gross heat of combustion of *exo*-THCPD is 19156 BTU/lb = 10642 cal/g, and the net heat of combustion is 18083 BTU/lb = 10046 cal/g [72].

### 23.2.7.6 Computational Chemistry of Thermodynamic Properties of *exo*-Tetrahydrodicyclopentadiene

Computational methods to estimate some physical and chemical properties, such as melting point, normal boiling point, standard enthalpy of vaporization at 298 K, standard enthalpy of formation at 298 K, standard enthalpy of combustion at 298 K, density, and flash point of polycyclic alkanes, were validated, despite the scarcity of experimental data, with several tens of polycyclic alkanes [299]. The methods were used to estimate properties of some polycyclic alkanes that are currently in use as missile fuels, such as JP-10, RJ-4, and RJ-5. Estimates and experimental data were found to be in good agreement for these fuels. This methodology was then used to evaluate new missile fuel candidates to be used in the pure state or as additives to JP-10 or to blends such as RJ-6.

The process of screening promising hydrocarbon propellants and eliminating less promising ones can be based on calculating the specific impulse of a rocket engine from the results of quantum-chemical calculation of their heats of combustion [148]. This approach ensures high accuracy irrespective of the composition and structure of the compounds under consideration. Polycyclic and framework hydrocarbons with small rings have been suggested as promising propellants.

Thermodynamic parameters for the parent *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane molecule and of all the tricyclodecyl radicals corresponding to the loss of hydrogen atoms from different carbon sites were determined using several DFT and composite computational chemistry methods [296]. The enthalpy of formation  $\Delta H_f^{o298}$  for *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane was predicted to be  $-81.6 \pm 5.4$  kJ/mol ( $-19.5 \pm 1.3$  kcal/mol), which is several kcal/mol lower than the commonly used values. Results from the use of five

different DFT methods were in very good agreement with composite level values for all reactions used for the radicals.

High-level *ab initio* calculations have been performed on the *exo* and *endo* isomers of gas-phase tetrahydrodicyclopentadiene (THDCPD), a principal component of JP-10, using Gaussian composite methods, as well as the CBS-QB3 method, and have been done using a variety of isodesmic and homodesmotic reaction schemes [297]. The impetus for this work was to resolve large discrepancies between literature data reported for the enthalpy of formation  $\Delta H_f^\circ(298)$  for *exo*-THDCPD. Isodesmic bond separation calculations for the *endo* isomer gave a heat of formation in excellent agreement with the experimental measurements. Combining calculated values for the gas-phase heat of formation with recent measurements of the heat of vaporization yields recommended values for  $\Delta H_f^\circ(298)_{\text{liq}}$  of  $-126.4$  and  $-114.7$  kJ/mol for the *exo* and *endo* isomers, respectively.

DFT calculations were performed to explore the molecular structure, electronic structure, C—H bond dissociation enthalpy, and reaction enthalpies for five isodesmic reactions of tetrahydrodicyclopentadiene [300]. On the basis of the calculations, it was found that the carbonium ion C-6 isomer formed from the catalytic cracking at the C6 site of tetrahydrodicyclopentadiene has the lowest energy, and the R-5 radical generated from the thermal cracking at the C5 site of tetrahydrodicyclopentadiene is the most stable isomer. A series of hypothetical and isodesmic work reactions containing similar bond environments was used to calculate the reaction enthalpies for target compounds. For the same isodesmic reaction, the reaction enthalpy of each carbon site radical was calculated. This method provided some valuable insights into the component design and energy utilization of advanced endothermic fuels.

### 23.2.8 Molecular Structure of *exo*-Tetrahydrodicyclopentadiene

The molecular structure of tetrahydrodicyclopentadiene is illustrated in Figure 33.

**Figure 33:** Simple plan view of tetrahydrodicyclopentadiene molecule

Alternate names for *exo*-tetrahydrodicyclopentadiene are tricyclo[5.2.1.0<sup>2,6</sup>]decane, *exo*-trimethylenenorbornane, *exo* isomer of 4,7-methano-1*H*-indene, octahydro 12a  $\alpha$ , 4 $\alpha$ , 7 $\alpha$ , 7a  $\alpha$ , CAS RN [2825-83-4] and [2825-82-3].

Tetrahydrodicyclopentadiene (THDCP, TCD) exists in either *exo* or *endo* form depending on the respective hydrogen atom/cyclopentane ring positions relative to the single CH<sub>2</sub> bridge carbon of the cyclohexane moiety in the molecule. In addition, there are chair and boat conformations for each of these two isomers. This results from the CH<sub>2</sub> group at C(4) position flop in this non-bridged cyclopentane ring; see Figure 34 for the position numbering scheme [296].

Figures 35 and 36 illustrate the *exo*- and *endo*-isomers along with their respective chair/boat conformations.

The molecular surface properties, including the molecular surface area and the positive, negative, and total average potentials, variances, average deviation, and electrostatic balance parameter on the molecular surface, were used for calculating the heats of vaporization and sublimation of 45 polycyclic saturated hydrocarbons with the general formula  $C_nH_n'$  ( $5 \leq n \leq 16$ ) in order to test 14 well-known isomers of tetrahydrodicyclopentadiene with molecular formulas of  $C_{10}H_{16}$  [301]. These properties were calculated using quantum chemical computational methods. For several compounds where experimental data were available, the agreement between predicted and published results was rather good. For polycyclic isomers of tetrahydrodicyclopentadiene, the highest values of heats of vaporization and sublimation were related to dispiro[2.2.2.2]decane and 1,7,7-trimethyltricyclo[2.2.1.0<sup>2,6</sup>]heptane, respectively. This method provided a suitable pathway to study phase transformations and molecular surface properties of polycyclic saturated hydrocarbon isomers.

DFT calculations were performed to explore the molecular structure, electronic structure, C—H bond dissociation enthalpy, and reaction enthalpies for five isodesmic reactions of *exo*-tetrahydrodicyclopentadiene [300].

### 23.2.9 Electrical Properties of *exo*-tetrahydrodicyclopentadiene

The dielectric constant of *exo*-tetrahydrodicyclopentadiene is 2.554, 2.489, 2.463, and 2.407 at 219, 273, 295, and 342 K (−65, 32, 72.5, and 156 °F) [72].

### 23.3 Fuel Mixtures with *exo*-Tetrahydrodicyclopentadiene

There are numerous fuel mixtures with tetrahydrodicyclopentadiene, the most prominent being RJ-6. RJ-6 is a blend of RJ-5 and JP-10 in the weight-percent ranges shown below. The nominal composition range was 58–64 mass-% perhydrodinorbornadiene (RJ-5) and 36–42 mass-% *exo*-tetrahydrodicyclopentadiene (JP-10).

Another fuel mixture consisted of 50 mass-% tetrahydromethylcyclopentadiene dimer (TH-dimer) with about 50 mass-% *exo*-tetrahydrodicyclopentadiene (*exo*-THDC, JP-10) [290]. The mixture exceeds U.S. Navy flash point requirements of 60 °C while yielding a lower viscosity than TH-dimer alone. Volumetric heating properties of the mixture make it an excellent ramjet fuel.

Other fuel mixtures described in the literature are tetrahydrodicyclopentadiene with *n*-undecane or *n*-tetradecane [302], *n*-nonane, *n*-dodecane or *n*-tridecane [303], cyclohexane, methylcyclohexane, ethylcyclohexane, butylcyclohexane or 1,2,4-trimethylcyclohexane [304], or isopropyl ether [305].

### 23.4 Chemical Properties of *exo*-Tetrahydrodicyclopentadiene

The chemical gross formula for *exo*-tetrahydrodicyclopentadiene (THDCPD) is C<sub>10</sub>H<sub>16</sub> with 11.84 mass-% hydrogen and a molecular mass of 136.24 g/mol. *Exo*-tetrahydrodicyclopentadiene is an isomer of adamantane, limonene, pinene, and camphene.

#### 23.4.1 Thermal Decomposition of *exo*-Tetrahydrodicyclopentadiene

This section overlaps significantly with Section 7.4.3 in the chapter “Jet Fuels” of *Encyclopedia of Liquid Fuels*, concerning the thermal decomposition of JP-10. Most investigators made no distinction between JP-10 and *exo*-tetrahydrodicyclopentadiene (THDCPD), but JP-10 may actually contain additives that influence its thermal decomposition and autoxidation behavior.

There are numerous publications about the thermal decomposition of THDCPD, and just as we have done in a preceding chapter on the thermal decomposition of JP-10, the literature references are given here in chronological order by the date of publication. The decomposition of JP-10 (tricyclo[5.2.1.0<sup>2,6</sup>]decane) was studied in a micro-flow-tube reactor in the temperature range 298 to 1300 K and on a millisecond time scale [306]. Decomposition was found to start at 840 K and was complete by the time the sample reached 1000 K. Thermal decomposition was compared to electron impact dissociation and chemical ionization of JP-10.

During an investigation of the thermal stability of *exo*-tetrahydrodicyclopentadiene (THDCPD), methylcyclohexane (MCH), and aviation kerosene RP-3, it was found that there was a maximum in the rate of thermal oxidation deposit formation at 473, 513, and 493 K (200, 240, and 220 °C) for RP-3, MCH, and THDCPD, respectively [307].

Pyrolytic deposits of three fuels increased dramatically and approximately followed an exponential function with the reaction temperature. The thermal stability of RP-3 was worst among the three fuels, while that of THDCPD was close to that of MCH, and THDCPD displayed even better thermal stability than that of MCH at high temperatures. Under SEM, the oxidation deposits and pyrolytic deposits of the three fuels showed different structure. Filamentous carbon, which contained metal particles that had been removed from the heat transfer surface, was found in the pyrolytic deposits of three fuels. This phenomenon was most obvious in the pyrolytic deposit of MCH.

The thermal decomposition of tricyclodecane was studied in a jet-stirred reactor at temperatures from 848 to 933 K for residence times between 0.5 and 6 s and at atmospheric pressure, corresponding to a conversion between 0.01 and 25% [308]. The main products of the reaction were hydrogen, methane, ethene, ethane, propene, 1,3-cyclopentadiene, cyclopentene, benzene, 1,5-hexadiene, toluene, and 3-cyclopentylcyclopentene. A primary mechanism containing all the possible initiation steps, including those involving diradicals as well as propagation reactions, has been developed and allows experimental results to be satisfactorily modeled. The main reaction pathways of consumption of tricyclodecane and of formation of the main products have been derived from flow rate and sensitivity analyses.

The effects of temperature and contact with metals on the thermal stability of *exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane (tricyclodecane, *exo*-THDCP) contained in a temperature-controlled batch reactor were investigated using GC/MS [309]. The surfaces of metals in contact with tricyclodecane were analyzed using SEM-EDAX. In the fuel temperature variation test, thermal decomposition of *exo*-THDCP took place at 623 K (350 °C). In the case of fuel in contact with metals, titanium was less catalytic to decomposition of *exo*-THDCP than stainless-steel CRES-304 or -316.

Thermal stability and the primary initiation mechanism of *exo*-tetrahydrodicyclopentadiene (*exo*-THDCP, C<sub>10</sub>H<sub>16</sub>) decomposition were investigated in a batch-type reactor [310]. The catalytic role of the stainless steel inside the reactor was eliminated by inserting a quartz flask. *Exo*-THDCP decomposed at temperatures over 623 K, and 1-cyclopentylcyclopentene (1-CPCP, C<sub>10</sub>H<sub>16</sub>) and 4-methyl-2,3,4,5,6,7-hexahydro-1*H*-indene (4-MHI, C<sub>10</sub>H<sub>16</sub>) were the primary decomposition products of *exo*-THDCP. C<sub>10</sub> hydrocarbons were determined to be the major products. The amounts of C<sub>5</sub>–C<sub>7</sub> hydrocarbons such as cyclopentene, benzene, and toluene were relatively small. A computer-based molecular modeling on some of the compounds, including 1-CPCP and 4-MHI produced from *exo*-THDCP, was done to evaluate the activation energy and molecular structure of the intermediates. The experimental and molecular modeling results showed that 1-CPCP and 4-MHI were independently formed from *exo*-THDCP. The experimental results closely corresponded with the molecular modeling result. The products that were only produced in small quantities after the reaction had qualitatively higher activation energies than the other products.

The thermal stability of *exo*-THDCP was investigated in the absence and presence of 1,2,3,4-tetrahydroquinoline (THQ), which acts as a hydrogen donor [311]. It

was found that conversion of *exo*-THDCP was faster at the higher temperature, which was to be expected. The increase in the rate of  $C_{<10}$  product formation with increasing temperature was higher than that of  $C_{\geq 10}$  product formation. Conversion of *exo*-THDCP was found to be slowed in the presence of THQ. The THQ-induced decrease in the conversion of *exo*-THDCP was smaller at the higher temperature. In addition, the THQ-induced decrease in the rate of  $C_{<10}$  product formation was smaller than that of  $C_{\geq 10}$ . A mechanism for the thermal decomposition of *exo*-THDCP was proposed, which explained the THQ-induced thermal stability improvement of *exo*-THDCP and suggested a mechanistic basis for developing effective additives capable of lowering decomposition product formation at high temperatures.

The thermal stability of *exo*-THDCP was investigated in the absence and presence of three additives, 3,4-dihydro-2*H*-1,4-benzoxazine (Benzox), THQ, and 1,2,3,4-tetrahydroquinoxaline (THQox), which act as hydrogen donors [312]. Conversion of *exo*-THDCP was slowed in the presence of hydrogen donors. The order of increasing H-donor effects on the decrease in the conversion of *exo*-THDCP was Benzox  $\ll$  THQ  $<$  THQox. The H-donor-induced decrease in the conversion of *exo*-THDCP was less pronounced at higher temperatures. In addition, the H-donor-induced decrease in the rate of  $C_{<10}$  product formation was smaller than that of  $C_{\geq 10}$ . A mechanism was proposed for the thermal decomposition of *exo*-THDCP in the presence of the H donor. The proposed mechanism explains the unusual thermal decomposition kinetics of *exo*-THDCP and H donors in the following way: **(1)** *exo*-THDCP does not follow first-order kinetics, and **(2)** THQ and THQox show the S-shaped concentration-time curves. A proposed mechanism for H donations by Benzox, THQ, and THQox elucidates that THQox performs faster H donation than THQ and has higher thermal stability than Benzox, which accounts for the more effective thermal stability improvement of *exo*-THDCP by THQox compared to THQ and Benzox.

During a further investigation of the decomposition of *exo*-tetrahydrodicyclopentadiene (*exo*-THDCP,  $C_{10}H_{16}$ ) in the absence and presence of  $O_2$  at various temperatures, it was found that the conversion of *exo*-THDCP was faster in the presence of  $O_2$  than in its absence [313]. The  $O_2$ -induced increase in the conversion of *exo*-THDCP was hardly affected by variations in temperature. In addition, the  $O_2$ -induced increase in the rate of  $C_{10}$  product formation was higher than those of  $C_{<10}$  and  $C_{>10}$  product formation. A mechanism was proposed for the oxidative decomposition of *exo*-THDCP, which occurs independently of its thermal decomposition and induces distinct product formation near and below its thermal decomposition starting temperature.

The thermal decomposition properties of *endo*-tetrahydrodicyclopentadiene, *exo*-tetrahydrodicyclopentadiene, tetrahydrotricyclopentadiene, and pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane were studied using DSC and thermogravimetric analysis (TGA)/differential thermogravimetry (DTG) [314]. The thermal decomposition products of pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane were identified by thermogravimetry-DSC-MS. The results showed that the decomposition of high-density hydrocarbon fuels is an endothermic process, and the endothermic heat

of decomposition increases with the pressure. The pyrolysis products are  $C_1$ – $C_5$  of alkanes, alkenes, and alkynes, etc., small molecular compounds. High-density hydrocarbons can be used as the components of endothermic hydrocarbon fuels.

The initial pathways of *exo*-tetrahydrodicyclopentadiene decomposition are expected to have a significant effect on combustion and pyrolysis behavior of the fuel, affecting, for example, product distribution and ignition delay [315]. Modeling of JP-10 decomposition should capture these initial decomposition processes as accurately as possible. Two classes of computational approaches have been applied to study intramolecular disproportionation, an important class of reactions in the initial stages of JP-10 decomposition: **(1)** the second-order, multi-configurational, quasi-degenerate perturbation theory employing the complete active space self-consistent field (CASSCF), and **(2)** the size-extensive, left-eigenstate, completely renormalized coupled-cluster method with singles, doubles, and non-iterative triples, termed CR-CC(2,3), capable of describing reaction pathways involving biradicals. With application of higher levels of theory to points along the CASSCF reaction paths, the barriers to intramolecular disproportionation are much smaller, and some barriers appear to vanish. The conventional ring-opening and disproportionation pathway was compared with an alternative concerted reaction pathway.

The pyrolysis of *exo*-TCD (*exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane) (3 vol.-% *exo*-TCD in argon) was performed in a flow-tube reactor at a temperature range of 900 to 1600 K under low pressure (667 Pa) [316]. The identification of products or intermediates and the distinction of stereoisomers were accomplished by synchrotron vacuum ultraviolet photoionization mass spectrometry (SVUV-PIMS). Approximately 28 species were identified and quantified by near-threshold measurements of photoionization mass spectra and photoionization efficiency spectra. The initial unimolecular decomposition rate of *exo*-TCD was estimated using transition states theory and Rice-Ramsperger-Kassel-Marcus (RRKM) theory. A detailed kinetic model of *exo*-TCD pyrolysis was developed including 316 species and 807 reactions. The simulation results generally agreed well with the experimental data. Rate of production and sensitivity analysis indicated that under lower pressure, the initial decomposition of *exo*-TCD proceeds dominantly by a diradical channel rather than the unimolecular decomposition or H-abstraction channels, and that the methyl-cyclic  $C_5$  and methylene-cyclic  $C_5$  species may be one of the principal precursors for the formation of aromatics (benzene, toluene).

*Exo*-tricyclo[5.2.1.0<sup>2,6</sup>]decane (TCD) or *exo*-tetrahydrodicyclopentadiene is an interesting strained-ring compound and is the main constituent or single-component of the high-energy density hydrocarbon fuel known as JP-10. Important initial reactions of TCD at high temperatures could cleave a strained carbon–carbon (C–C) bond in the ring system, thereby creating diradicals also constrained by the remaining ring system. The thermochemical properties of these diradicals (TCD-H 2mJ-nJ where m and n correspond to the cleaved carbons sites) including the carbon–carbon bond dissociation energy (C–C BDE) corresponding to the cleaved TCD site, were inves-

tigated [317]. Thermochemical properties, including enthalpies ( $\Delta H_f^{298}$ ), entropies, heat capacities, and C—H and C—C BDEs for the parent (TCD-H2 m-n), radical (TCD-H2 mJ-n and m-nJ), diradical (TCD-H 2mJ-nJ), and carbene (TCD-H 2mJJ-n and m-nJJ) species, were determined by computation. Structures, vibrational frequencies, moments of inertia, and internal rotor potentials were calculated. Standard enthalpies of formation in the gas phase for the TCD-H 2m-n parent and radical species were predicted using DFT and the higher-level composite methods. The bond energies calculated with these methods were shown to be comparable to those obtained by other calculation methods. C—C bond dissociation energies ranged from 324 to 354 kJ/mol (77.4 to 84.6 kcal/mol) for TCD diradical singlet species. C—H BDEs for the parent TCD-H 2m-n carbon sites ranged from 389 to 423 kJ/mol (93–101 kcal/mol), with a similar range seen for loss of the second hydrogen to generate the diradical singlet species.

Two sets of experiments were performed to study the high-temperature pyrolysis of tricyclo[5.2.1.0<sup>2,6</sup>]decane (JP-10) using high-temperature reactors over temperature ranges of 1100 to 1600 K and 927 to 1083 K, with residence times of a few tens of microseconds to, typically, 144 ms [318].

### 23.4.2 Catalyzed Decomposition of *exo*-Tetrahydrodicyclopentadiene

The catalytic cracking of tricyclo [5.2.1.02.6] decane (JP-10) over HZSM-5 molecular sieves with different Si/Al mole ratios was investigated over a temperature range from 773 to 873 K [319]. This reaction of an endothermic fuel is of interest for the cooling of hypersonic flight vehicles. Compared with the thermal cracking and the catalytic cracking over ZSM-5, conversions of JP-10 from the catalytic cracking over HZSM-5 molecular sieves at the same temperature were more rapid. The predominant hydrocarbon products from the catalytic cracking, analyzed at room temperature and atmospheric pressure, were methane, ethane, ethene, propane, and propylene in the gaseous phase and benzene, indene, naphthalene, and their homologues in the liquid phase. The contents of ethane, propane, and propene decreased with increasing Si/Al mole ratio of a catalyst, while those of methane and ethene increased simultaneously with the increase of Si/Al mole ratio of HZSM-5. The contents of the main components in the liquid products produced on the catalyst surface at a given temperature also decreased with the increase of Si/Al mole ratio. A HZSM-5 catalyst with a high Si/Al mole ratio could be chosen to obtain high yields of alkenes.

The thermal decomposition of *exo*-tetrahydrodicyclopentadiene (*exo*-THDCP, C<sub>10</sub>H<sub>16</sub>) was investigated in the absence and presence of various metals, Ti, SS316, SS304, Fe, Ni, and Cu [320]. It was found that conversion of *exo*-THDCP was faster in the presence of metals compared to tests conducted in the absence of metals. The increasing order of the metal catalytic effects on the increase in the conversion of *exo*-THDCP was Ti < SS316 < SS304 < Fe < Ni < Cu. The metal-induced increase in the conversion of *exo*-THDCP was more pronounced at the higher temperature. In addition, the metal-induced increases in the rates of C<sub>5–9</sub>, C<sub>15–</sub>, and C<sub>sd</sub> product for-

mations were higher than those of  $C_{\leq 4}$  and  $C_{10-14}$ . The composition and crystallinity of metal surfaces were found to be associated with the distinct metal effects on the thermal decomposition of *exo*-THDCP.

Catalytic endothermic reactions of *exo*-tetrahydrodicyclopentadiene (*exo*-THDCP) with different zeolites were investigated in a batch reactor to increase the rates and change the product distribution of endothermic reactions [321]. The heat of reaction with each zeolite was calculated by the NIST SUPERTRAPP program. The conversion and product distribution were investigated because they affected the heat of reaction. The heat of reaction of HZSM-5 was greater than those of other zeolites due to its total acid density and pore structures. It showed the highest conversion and highest composition percentage of low molecular weight products. Because dehydrogenation can increase endothermic heat, Pt/HZSM-5 (1 mass-% Pt loaded) was used in the endothermic reaction. The metal sites led to the dehydrogenation of saturated hydrocarbons and an increase in olefins. High conversion and high yields of low molecular weight hydrocarbons and olefins were necessary to increase the overall heat of reaction.

### 23.4.3 Computational Modeling of *exo*-Tetrahydrodicyclopentadiene Decomposition

The initial pathways of *exo*-tetrahydrodicyclopentadiene decomposition are expected to have a significant effect on the combustion and pyrolysis behavior of the fuel, affecting, for example, product distribution and ignition delay [315]. Modeling of *exo*-tetrahydrodicyclopentadiene decomposition should capture these initial decomposition processes as accurately as possible. Two classes of computational approaches have been applied to study intramolecular disproportionation, an important class of reactions in the initial stages of *exo*-tetrahydrodicyclopentadiene decomposition: **(1)** the second-order, multi-configurational, quasi-degenerate perturbation theory employing the complete active space self-consistent field (CASSCF) reference, and **(2)** the size-extensive, left-eigenstate, completely renormalized, coupled-cluster method with singles, doubles, and non-iterative triples, termed CR-CC(2,3), capable of describing reaction pathways involving biradicals. With the application of higher levels of theory to points along the CASSCF reaction paths, the barriers to intramolecular disproportionation were much smaller, and some barriers appeared to vanish. The conventional ring-opening and disproportionation pathway was compared with an alternative concerted reaction pathway.

The  $C < 5$  products predicted by molecular dynamics simulations were consistent with those detected using experimental techniques [322]. Particularly, the product evolution tendency of methane, ethane, ethylene, propylene, acetylene, allene, 1-butene, propyne, 1,3-butadiene, and cyclopentadiene with temperature was in good agreement with the results of single-pulse shock tube experiments. The simulation results indicated that JP-10 pyrolysis reactions proceed in three stages: the initial ring-opening through C—C bond homolysis in stage I, the initiation and growth of

chain radicals through  $\beta$ -scission reactions as well as chain propagation via C—H bond scission in stage II, and the chain propagation through further C—H bond cleavage and the chain termination reactions in stage III.

#### 23.4.4 Oxidation of *exo*-Tetrahydrodicyclopentadiene

Traces of oxygen have been identified as having a pronounced effect on the onset of thermal decomposition of many hydrocarbons.

The exothermicity of oxidation of *exo*-tetrahydrodicyclopentadiene ultimately leads to ignition of the fuel if sufficient air or oxygen is present. The kinetics of oxidation of *exo*-tetrahydrodicyclopentadiene is discussed here, while actual combustion properties (ignition energy, flame speed, detonation speed) will be discussed in a future *Encyclopedia of Nonhypergolic Bipropellant Combinations*.

The ignition of JP-10 was examined from computational and theoretical viewpoints [323]. A detailed chemical mechanism consisting of 174 elementary steps among 36 chemical species was obtained by adding 27 steps, including JP-10, cyclopentene, and 1,3-butadiene, to an earlier scheme. See also [324]. The ignition of *exo*-tetrahydrodicyclopentadiene droplets in air is different if the fuel is doped with aluminum nanoparticles to enhance its fuel value [325].

#### 23.4.5 Analysis of *exo*-Tetrahydrodicyclopentadiene

The constituents of four types of JP-10 were analyzed using GC/MS [326]. The purity of JP-10 fuels was measured with an external standard method. Results showed that JP-10 contained not only the main component *exo*-tetrahydrodicyclopentadiene but also decahydronaphthalene, *endo*-tetrahydrodicyclopentadiene, adamantane, and their methylated derivatives. The suitable concentration range for external standard method to measure the purity of JP-10 is 0.5–20 mg/mL.

### 23.5 Safety Properties of *exo*-Tetrahydrodicyclopentadiene

The flash point of JP-10 is 327.5 K (54.4 °C), and it is assumed that the flash point of *exo*-tetrahydrodicyclopentadiene would be the same. One sample of *exo*-tetrahydrodicyclopentadiene had a flash point of 329 K (56 °C) [290].

## 24 Tetrahydrodimethyldicyclopentadiene

Tetrahydrodimethyldicyclopentadiene, C<sub>12</sub>H<sub>20</sub>, CAS RN [26472-00-4], is the main ingredient of RJ-4. The properties of RJ-4 are described in the chapter “Ramjet Fuels” of *Encyclopedia of Liquid Fuels*.

In the following section are listed the properties of the pure compound tetrahydromethylcyclopentadiene, not those of the RJ-4 mixture.

### 24.1 Production of Tetrahydromethylcyclopentadiene

Tetrahydromethylcyclopentadiene can be prepared by hydrogenation of dimethylcyclopentadiene, followed by isomerization.

The precursor, dimethylcyclopentadiene, can be prepared by dimerization of methylcyclopentadiene. Both the hydrogenation and the isomerization steps use a nickel on silica-alumina catalyst [327]. The temperature of the hydrogenation should be in the range of about 343–533 K (70–260 °C) and the temperature of the isomerization in the range of about 473–553 K (200–280 °C) [328]. The pressure range for hydrogenation is about 1.38–20.7 MPa (200–3000 psig) and for isomerization is between 0.07 and 10.3 MPa (10–1500 psig). Hydrogen is present during the isomerization.

*Endo*-tetrahydromethylcyclopentadiene isomers within the raw fuel stock can be isomerized to *exo*-isomers by treatment of the fuel stock with catalysts such as aluminum chloride, nickel, or pulverized, acid-treated firebrick, resulting in a fuel with a lower viscosity than the original raw fuel stock [329].

Tetrahydromethylcyclopentadiene can be catalytically isomerized to a liquid isomeric mixture having a suitable low temperature viscosity, making it suitable as a missile fuel. One catalyst proposed for the isomerization was an acidic alumina. Hydrogen was also kept present and in an amount sufficient to maintain the isomerization activity of the alumina. Moderately elevated temperature is sufficient to cause isomerization. The temperature of the isomerization is in the range of about 473–553 K (200–280 °C) [328].

The kinetics of hydrogenation of methylcyclopentadiene dimer (MCPD) to *endo*-tetrahydromethylcyclopentadiene over Pd/C catalysts were investigated, and the reactivity of the C=C bond in the MCPD molecule was analyzed using DFT calculations [330]. A kinetic model was developed based on the Langmuir-Hinshelwood mechanism with the consideration of the non-competitive adsorption between the organic species and atomic hydrogen. The model parameters were obtained by fitting experimental data at differential temperatures using the non-linear least squares and Runge-Kutta methods. The reaction activation energies for the two steps of hydrogenation

were 22.86 and 41.21 kJ/mol. The good correlation between the kinetic model and the experimental data contributed to a better understanding of the consecutive hydrogenation mechanism of high-density polycyclic hydrocarbon fuels.

## 24.2 Physical Properties of Tetrahydrodimethyldicyclopentadiene

The physical properties of tetrahydrodimethyldicyclopentadiene depend on the proportions of stereoisomers, in particular the ratio of *endo*- to *exo*-isomers. The *endo* isomers have higher melting points and may solidify at room temperature. There are only a few exact physical property data for the isolated isomers with a clean structure. Pure compounds are not required for the RJ-4 application. The two structural isomers shown in Figure 37 are liquids at room temperature, while other, undesirable isomers are solids and not suitable as liquid fuels.

**Figure 37:** Molecular structure of tetrahydrodimethyldicyclopentadiene isomers

## 24.3 Chemical Properties of Tetrahydrodimethyldicyclopentadiene

The empirical, gross chemical formula of tetrahydrodimethyldicyclopentadiene is  $C_{12}H_{20}$ , with a hydrogen content of 12.27 mass-% and a molecular mass of 164.29 g/mol.

## 25 Tricyclopentadiene

Tricyclopentadiene, also known as  $C_{15}H_{18}$ , cyclopentadiene trimer, TCPD; 4,9:5,8-dimethano-1*H*-benz[*f*]indene, 3a,4,4a,5,8,8a,9,9a-octahydro-; CAS RN [7158-25-0], is a by-product of the synthesis of dicyclopentadiene.

### 25.1 Production of Tricyclopentadiene

Tricyclopentadiene, a product of dicyclopentadiene/cyclopentadiene cycloaddition, is a precursor for synthesis of a high-energy-density fuel, tetrahydrotricyclopentadiene. Tricyclopentadiene can be prepared by heating feed streams containing dicyclopentadiene or cyclopentadiene or mixtures of the two [331]. The yield of tricyclopentadiene is better if the feed stream is mostly dicyclopentadiene, for instance 50% dicyclopentadiene in benzene as the process solvent. The reactor temperature should be between 533 and 583 K (260 and 310 °C) because no trimerization occurs below 533 K (260 °C), and temperatures above 583 K (310 °C) lead to undesirable tetramers and higher oligomers. The residence time in the reactor zone should be 10–20 min.

Mixtures of cyclopentadiene and methylcyclopentadiene dimers can be co-reacted at 483 K (210 °C) for 1 h to generate a mixture of trimers that can subsequently be hydrogenated to give a high-density fuel, tetrahydrotricyclopentadiene, with a density of 1.018 g/cm<sup>3</sup> and a freezing point below 219 K (–65 °F) [332].

Nearly total suppression of the unwanted dimerization and selective trimerization of cyclopentadiene can be achieved by a mixed catalyst formed from a palladium complex, a phosphane, and a carboxylic acid [333]. The cyclopentene ring attached to the norbornane system of the trimers 1a, 1b is in the endo conformation and differs only in the location of the double bonds.

The processes of homo-oligomerization and co-oligomerization of dicyclopentadiene were investigated on the laboratory and pilot-plant scale under controlled isothermal or boiling conditions [243]. Reaction conditions and their effect on the quality of products were optimized. The oligomerization of dicyclopentadiene can proceed by two different mechanisms: **(1)** the Diels-Alder polyaddition at temperatures below 473 K (200 °C) and **(2)** thermal oligomerization at temperatures close to 533 K (260 °C). Products obtained by these two mechanisms differed significantly in their physical properties. Realistic models of Diels-Alder and thermal oligomerization processes considering reversible reaction kinetics and vapor-liquid-phase equilibrium were developed.

Pressure and the presence of high-boiling process solvents had an effect on the Diels-Alder oligomerization process and product properties.

Oligomerization reactions of cyclopentadiene and dicyclopentadiene are discussed in Section 22.5.3. Tricyclopentadiene can be made by oligomerization of *endo*-dicyclopentadiene at elevated pressure [244, 245, 334].

Thermal  $[4 + 2]$  cycloaddition of dicyclopentadiene/cyclopentadiene was simulated using a computer program to predict the product distribution [335]. There are four concerted but slightly asynchronous pathways leading to four adducts for *endo*-dicyclopentadiene/cyclopentadiene and *exo*-dicyclopentadiene/cyclopentadiene additions, respectively. The pathways connecting *endo*-adduct are kinetically preferred compared with those connecting *exo*-adduct. Norbornadiene-adducts showed higher stability than corresponding cyclopentadiene adducts. *Exo*-isomers are more stable for cyclopentadiene adducts, but the tendency is inverse for norbornadiene adducts.

Tricyclopentadiene was synthesized by oligomerization of dicyclopentadiene and cyclopentadiene, with a yield up to 83.2% [336]. A study of the effects of catalyst amount, temperature, and type of solvent on the reaction showed that the optimum conditions were a molar ratio of  $[\text{Ni}(\text{PPh}_3)_2]\text{Cl}_2:\text{Zn}:\text{cyclopentadiene} = 0.05:0.6:1$ , reaction temperature 333 K (60 °C), and reaction duration 8 h. Compared to the Diels-Alder method, the oligomerization method proceeds at a lower reaction temperature and pressure (0.1 MPa) and gives a higher yield.

Cyclopentadiene trimer (tricyclopentadiene) is an important raw material for the synthesis of high-energy-density fuels. Tricyclopentadiene can be synthesized through a  $[4 + 2]$  cycloaddition between *endo*-dicyclopentadiene and cyclopentadiene over microporous zeolites (ZSM-5, HY) and mesoporous Al-MCM-41 catalysts [337]. The catalytic activity was strongly influenced by the average pore size and the Brønsted acidity of the catalyst. Of the several catalysts tested, an  $\text{NH}_4\text{F}$ -treated Al-MCM-41 catalyst, which had meso-sized pores (3.4 nm in average) and enhanced Brønsted acidity, exhibited the best dicyclopentadiene conversion, tricyclopentadiene selectivity, and yield. The average pore size of the catalyst influenced the isomer distribution of the tricyclopentadiene products. The mesoporous catalysts produced mixtures of *exo*- and *endo*-tricyclopentadiene, which favored the *exo*-fraction (approximately 40 mol-%) compared to the microporous catalysts (approximately 20 mol-%).

Homogeneous palladium catalysts enable the  $[2 + 2]$  isomer synthesis of tricyclopentadiene in good yield (up to 98% from cyclopentadiene and up to 78% from dicyclopentadiene) with high selectivity. The effects of a variety of palladium precursors, phosphorus ligands, and acids were investigated to improve the productivity and selectivity of the tricyclopentadiene synthesis [338]. The reaction conditions were optimized, and their effects on the product distribution were evaluated.

Tricyclopentadiene is one of the precursors for making tetrahydrotricyclopentadiene, a fuel with high energy density. Tricyclopentadiene was obtained by polymerization reaction of DCPD using ionic liquid-supported mesoporous silica catalysts [339].

Ionic liquid-supported mesoporous silicas showed better catalytic performance with regard to tricyclopentadiene yield and dicyclopentadiene conversion than those not using ionic liquids. Among four kinds of ionic liquid-supported mesoporous silica catalysts, the CuCl-based ionic liquid-supported MCM-41 system showed the highest tricyclopentadiene yield.

The catalytic potential of metal oxide/MCM-41 catalysts, including molybdenum oxide, tungsten oxide, and titanium oxide on MCM-41, for the dicyclopentadiene oligomerization and dicyclopentadiene oligomer isomerization was evaluated [340]. The number of acid sites with weak strength were increased through metal oxide deposition. The oligomer yield in dicyclopentadiene oligomerization and dicyclopentadiene oligomer isomerization did not change with an increasing number of acid sites. The highest tricyclopentadiene isomer selectivity over the MoO<sub>3</sub>/MCM-41 catalyst could be attributed to having the highest overall number of acid sites among the several catalysts tested.

A catalyst composed of microporous and mesoporous material prepared from ferrierite was evaluated as a catalyst for oligomerization of *endo*-dicyclopentadiene (DCPD) [341]. Physical and chemical characteristics of the catalysts were analyzed using NH<sub>3</sub>-TPD, N<sub>2</sub> adsorption, XRD, and IR spectroscopy of adsorbed pyridine. The catalyst showed a weak acid site composed of Brønsted acid site, Lewis acid sites, and H acid sites, whereas strong acid sites were not observed. In the case of the dicyclopentadiene oligomerization that utilized this catalyst, the yield of tricyclopentadiene and tetracyclopentadiene reached 30.4 and 19.9%, respectively, which were higher than those obtained with other catalysts. This is a good catalyst for the isomerization selectivity to *exo*-tricyclopentadiene. Weak acid sites on this catalyst play a role as active sites for *endo*-dicyclopentadiene oligomerization. The higher activity in dicyclopentadiene oligomerization is probably due to the large pore size of this catalyst.

The oligomerization of *endo*-dicyclopentadiene (*endo*-DCPD) over a mesoporous catalyst in a continuous-flow reactor at elevated pressure was studied to produce tricyclopentadiene (TCPD) and tetracyclopentadiene (TeCPD) [342]. A mesoporous material prepared from a zeolite was used as a catalyst. TCPD and TeCPD were continuously produced through DCPD oligomerization over the zeolite catalyst in a fixed-bed reactor. At early time-on-stream, the conversion of *endo*-DCPD, the yield of TCPD and TeCPD, and the isomerization selectivity of TCPD in the fixed-bed reactor were comparable to those in a batch-type reactor. The yield of oligomer containing TCPD and TeCPD decreased drastically from 28.5% at 3 h time-on-stream to 21.5% at 12 h time-on-stream, indicating that the catalyst was being deactivated, but *in situ* calcination in air flow at 773 K (500 °C) was found to be effective for the regeneration of the used catalyst.

## 25.2 Physical Properties of Tricyclopentadiene

There are no summaries of physical properties of tricyclopentadiene in the literature. It is difficult to obtain samples with pure isomers for physical property determination. The molecular structures of three possible isomers of tricyclopentadiene are shown in Figure 38.

**Figure 38:** Three possible isomers of tricyclopentadiene

## 25.3 Chemical Properties of Tricyclopentadiene

The hydrogenation of tricyclopentadiene results in the formation of tetrahydrotricyclopentadiene. Therefore, the publications dealing with this reaction will be discussed in the following section.

## 26 Tetrahydrotricyclopentadiene

Tetrahydrotricyclopentadiene, *exo*-THTC, THTCPD,  $C_{15}H_{22}$ , CAS RN [56086-31-8], exists in several stereoisomers, of which the *exo*-conformer is the one with importance as a candidate high-density fuel, a possible successor to and future replacement of JP-10 with even better properties. Other names for this compound are 4,9:5,8-dimethano-1*H*-benz[*f*]indene, dodecahydro-; 4,9,5,8-dimethano-1- $\beta$ -naphthindene, dodecahydro- (3CI); and dodecahydro-4,9:5,8-dimethano-1*H*-benz[*f*]indene.

## 26.1 Preparation of Tetrahydrotricyclopentadiene

As the first step in this synthesis, dicyclopentadiene is heated in a closed system to 443 K (170 °C), forming tricyclopentadiene, tetracyclopentadiene, and pentacyclopentadiene as products. The reaction mixture is distilled, and the 438–448 K (165–175 °C) fraction is then hydrogenated in the presence of a Ni/kieselguhr catalyst, giving a mixture of stereoisomers [343]. Isomerizing the *endo*-tetrahydrotricyclopentadiene by treatment with aluminum chloride at a temperature from 273 to 293 K (0 to 20 °C) in a methylene chloride solvent forms the desired *exo*-tetrahydrotricyclopentadiene, a low-freezing, high-density liquid fuel.

Pd – B/γ-Al<sub>2</sub>O<sub>3</sub> amorphous catalysts were prepared through impregnation and KBH<sub>4</sub> reduction and then used for the hydrogenation of tricyclopentadiene [344]. The kinetics of tricyclopentadiene hydrogenation to tetrahydrotricyclopentadiene over Pd – B/γ-Al<sub>2</sub>O<sub>3</sub> amorphous catalyst was studied in a stirred semi-batch reactor over a range of temperatures (353–413 K), hydrogen pressures (1.0–3.5 MPa), initial feed concentrations (0.2–0.4 mol/L), and catalyst concentrations (0.60–5.33 g/L) [345]. The reaction was found to be a consecutive reaction, with 14,15-dihydrotricyclopentadiene as the intermediate product. Analysis verified that the kinetic experiments were conducted in the absence of mass transfer resistance. A kinetic model was formulated with the assumptions that single-site adsorbed organic species are saturated by hydrogen dissolved in the liquid phase and that the surface reaction is rate-determining. This model was able to accurately fit the experimental data in the ranges studied and correctly explained the observed tendencies. The activation energies for the first-step and second-step reactions were 11.11 and 34.71 kJ/mol, respectively.

Crystallized Pd – B/γ-Al<sub>2</sub>O<sub>3</sub> catalysts were obtained by thermal treatment of the prepared amorphous catalyst at elevated temperatures. For comparison, a conventional H<sub>2</sub>-reduced Pd/γ-Al<sub>2</sub>O<sub>3</sub> catalyst was also prepared. The catalysts were characterized by inductively coupled plasma, XRD, SEM, TEM, DSC, and TPD, and were used for the hydrogenation of tricyclopentadiene [346]. All the catalysts demonstrated similar activities for partial hydrogenation of tricyclopentadiene to dihydrotricyclopentadiene. However, the amorphous alloy catalyst showed significantly higher activity for the further hydrogenation of dihydrotricyclopentadiene to the final product tetrahydrotricyclopentadiene.

Tetrahydrotricyclopentadiene has been prepared by the reaction of dicyclopentadiene with cyclopentadiene by first reacting dicyclopentadiene with cyclopentadiene to produce tricyclopentadiene, which was then converted into the final product in the presence of H and Raney nickel [347]. A study of the effects of temperature, pressure, and reaction time as well as the solvent amount on conversion and yield showed that the optimal conditions were a temperature of 493 K (220 °C), a pressure of 0.5 MPa, a solvent concentration of 50 mass-%, and a reaction duration of 4 h. Under these conditions, the conversion of dicyclopentadiene was 85.4%, and the yield of tetrahydrotri-

cyclopentadiene was able to reach 76.5%. The last step of the process, the reaction of tricyclopentadiene with hydrogen, promoted by Raney nickel, achieved a high yield of tetrahydrotricyclopentadiene of 99.6%.

The reaction intermediate and final products of the hydrogenation of tricyclopentadiene (TCPD) were characterized using GC-MS, IR,  $^1\text{H}$  NMR, and  $^{13}\text{C}$  NMR [348]. The double bond in the norbornene ring (NB bond) of TCPD was easily saturated at a low temperature, and an intermediate 12,13-dihydrotricyclopentadiene (12,13-DHTCPD) was formed. Higher temperature and hydrogen pressure were required for the saturation of the remaining double bond in the cyclopentene ring (CP bond) to generate a completely hydrogenated compound tetrahydrotricyclopentadiene (THTCPD). A DFT calculation was conducted by using Gaussian 03 series programs to clarify the reactivity of double bonds in TCPD molecules. The bond parameters confirmed that the NB double bond was more reactive than the CP bond. Total energy calculation also showed that 12,13-DHTCPD was thermodynamically preferred, compared with the other possible intermediate 5,6-DHTCPD. The computational result was in good agreement with the experiments.

THTCPD was synthesized from dicyclopentadiene and indene by a Diels-Alder reaction and hydrogenation [349]. The density of THTCPD thereby obtained was  $1.082\text{ g/cm}^3$ . The volumetric heat of combustion was  $47.5\text{ MJ/L}$ . The flash point was  $393\text{ K}$  ( $120^\circ\text{C}$ ), and the melting point was  $321\text{--}322\text{ K}$  ( $48\text{--}49^\circ\text{C}$ ). Thermal decomposition of THTCPD was studied in a decomposition reactor at atmospheric pressure in the temperature range of  $973$  to  $1153\text{ K}$ . Decomposition products detected by GC/MS were methane, ethene, propylene, cyclopentene, cyclopentadiene, benzene, and toluene. The conversion of THTCPD at different temperatures was investigated. A primary mechanism including nine pathways was proposed according to the main products of the reaction and a monoradical mechanism. DFT calculations of the potential energy surface were performed to investigate the mechanisms of THTCPD breakdown, and relative energy and ratio of reaction routes were computed. The kinetic equation of thermal decomposition was obtained by relation of the conversion and temperature. The pre-exponential factor and activation energy overall reaction order for thermal cracking of THTCPD were determined by linear regression analysis to be  $133.75$  and  $6.67 \times 10^4\text{ kJ/mol}$ , respectively.

*Exo*-tetrahydrotricyclopentadiene (*exo*-THTCPD) has a high volumetric energy content ( $43.2\text{ MJ/L}$ ), high density ( $1.04\text{ g/mL}$ ), and low freezing point ( $233\text{ K} = -40^\circ\text{C}$ ). A one-pot catalytic synthesis of *exo*-THTCPD directly from dicyclopentadiene (DCPD) was performed in one-pot in three steps [350]. First, tricyclopentadiene (TCPD) was prepared directly from the dissociation-recombination of DCPD at  $473\text{ K}$  ( $200^\circ\text{C}$ ). Then the reaction mixture (the majority being TCPD, mixed with small amounts of DCPD and tetracyclopentadiene) was hydrogenated using supported noble metal catalysts at  $423\text{ K}$  ( $150^\circ\text{C}$ ) under  $4.0\text{ MPa}$  hydrogen. Finally, the hydrogenated mixture was treated by  $\text{AlCl}_3$ -catalytic isomerization at  $288\text{ K}$  ( $15^\circ\text{C}$ ). Fractionated distillation was needed to obtain the final product of *exo*-THTCPD. See also [351].

THTCPD can be produced by the hydrogenation of TCPD using ruthenium/nanoporous silica catalysts for TCPD hydrogenation [352]. Ru/KIT-6 and Ru/SBA-15 catalysts showed significantly higher activity compared to Ru/kieselguhr catalyst during TCPD hydrogenation. The nanoporous structures of Ru/KIT-6 and Ru/SBA-15 help overcome the diffusion limitations of reactants and products during the TCPD hydrogenation process. In addition to the diffusion factors, the distribution of ruthenium crystallites on the support plays an important role in the TCPD hydrogenation activity.

## 26.2 Isomerization of Tetrahydrotricyclopentadiene

Mixed *endo*- and *exo*-tetrahydropolycyclopentadienes can be isomerized in the presence of anhydrous aluminum trichloride,  $\text{AlCl}_3$ , to produce a high-energy missile fuel [353]. The amount of aluminum trichloride present is such that its weight ratio to tetrahydropolydiene is in the range of about 0.005 to about 0.75. The isomerization is carried out in an inert solvent in the presence of anhydrous hydrogen chloride and at a temperature between 253 and 298 K (−20 and +25 °C).

Aluminum trichloride was used as a catalyst to transform a THTCPD mixture into a high-energy-density liquid fuel [354]. The reactant contained three inseparable isomers (I, II, and III) to start with. Quantum computations showed the possibility of *endo* fragments of THTCPD turning into *exo* counterparts. However, experiments indicated that the isomerization only happens on norbornyl fragments, and cyclopropyl fragments remain unchanged. Reactants I and II containing both norbornyl and cyclopropyl fragments were only slowly isomerized, and the reactions are reversible, whereas component III without a cyclopropyl fragment was converted quickly. A 5% concentration of  $\text{AlCl}_3$  showed enough catalytic activity. A temperature higher than 288 K (15 °C) is not preferred because it lowers the equilibrium conversion. A halohydrocarbon solvent such as 1,2-dichloroethane is necessary. Pseudo-first-order reversible kinetics was established for the isomerization of I and II. The heat of reaction was 22.94 and 17.69 kJ/mol, respectively. The resulting mixture showed good potential as a fuel for advanced propulsion due to its high energy content and low freezing point.

Instead of using aluminum chloride for the catalytic isomerization of THTCPD, the use of chloroaluminate ionic liquid catalysts gave a totally different product distribution [355]. The *endo*-cyclopropyl fragments of THTCPD that cannot be isomerized by  $\text{AlCl}_3$  catalysis were easily transferred to the desirable *exo* conformation. The hydrocarbons were transferred to diamondoids as by-products, including methyl-1,2-tetramethyleneadamantane, methyl-diethyl-adamantane, and methyl-diamantane via skeletal rearrangement, with the first diamondoid as the primary and dominant product (selectivity 80%). The ionic liquid showed much higher activity than superacid  $\text{CF}_3\text{SO}_3\text{H}$ . Increasing the temperature, ionic liquid dosage, and

addition of  $\text{AlCl}_3$  can promote the rearrangement rate with a slight decrease in the selectivity of methyl-1,2-tetramethylenadamantane. The diamondoid-based product had a low freezing point and high hydrogen content and thus would be superior as a high-energy-density fuel.

The ionic liquid-catalyzed isomerization of tetrahydrotricyclopentadiene can also be achieved using various chloroaluminate complexes [356], Y zeolites [281], copper(I) chloride or iron(III) chloride in ionic liquids [357] or chloroaluminate ionic liquid catalysts [358].

The isomerization of *endo*- to *exo*-tetrahydrotricyclopentadiene over alumino-silicate catalysts (ZSM-5, MOR, HY, Cu-HY, Al-MCM-41) was evaluated using a batch reactor, and the catalytic performances were significantly affected by the microchannel or pore size, acid strength, and acid type of each catalyst [359].  $\text{N}_2$  adsorption-desorption,  $\text{NH}_3$ -temperature-programmed desorption, and pyridine FTIR analyses indicated that the pore size of the catalyst and the acid strength on the catalyst surface affected the conversion rate of *endo*-THTCPD, and the type of acid on the catalyst surface affected the *exo*-THTCPD selectivity. The HY catalyst showed the highest yield and productivity among all of the catalysts evaluated.

The reaction conditions for a facile route to synthesize alkyl-diamondoids via solvent-free rearrangement of tetrahydrotricyclopentadiene catalyzed by acid were optimized, varying catalysts, temperature, catalyst dosage, and process solvent [360]. Notably, under the optimal conditions (10.7 mass-% catalyst, 453 K = 180 °C, 20 h), an extremely high content of alkyl-diamondoids (85.6%) was found in liquid phase, and a high carbon yield of alkyl-diamondoids (60.0%) was obtained. The reaction kinetics of rearrangement were investigated, and the reaction rate constants and apparent activation energies were calculated based on the experimental kinetic data. The resultant diamondoid-based product showed excellent low-temperature performance and a higher energy content than reported for diamondoids and widely used JP-10 fuel, and thus would be superior as a high-energy-density fuel.

The oligomerization of cyclopentadiene and dicyclopentadiene to tricyclopentadiene through the Diels-Alder reaction at temperatures between 393 and 423 K (120 and 150 °C) depends on the type of solvent used in the process [361]. A study showed that the reaction temperature has the most pronounced effect on the reaction, and at a lower reaction temperature near 403 K (130 °C), pressure has a considerable effect on the oligomerization. The use of different solvents had a totally different effect on the reaction in that it changed the reaction rate of conversion, yield, and product composition. Without higher oligomers, the oligomerization showed high selectivity at any given reaction temperature. These findings are similar to the solvent effects observed during the isomerization of *endo*-THDCPD to *exo*-THDCPD [275].

A homologue of tetrahydrotricyclopentadiene, tricycloundecane, has similar isomerization behavior [362]. Tricycloundecane is an intermediate in the formation of adamantane.

## 26.3 Physical Properties of Tetrahydrotricyclopentadiene

*Exo*-tetrahydrotricyclopentadiene (*exo*-THTC) has a freezing point less than 233 K (less than  $-40^{\circ}\text{C}$ ), a density of  $1.0376\text{ g/cm}^3$ , a flash point of 424 K ( $151^{\circ}\text{C}$ ), and viscosity of 37 cPs at 293 K ( $20^{\circ}\text{C}$ ), 97 cPs at 273 K ( $0^{\circ}\text{C}$ ), and 510 cPs at 253 K ( $-20^{\circ}\text{C}$ ). The net heat of combustion is  $\Delta H_{\text{comb}} = 42095\text{ kJ/kg}$  ( $18110\text{ BTU/lb}$ ) [343].

There are about 14 structural and stereo isomers for tetrahydrotricyclopentadiene [363]. Five examples of possible molecular structures of tetrahydrotricyclopentadiene are shown in Figure 39.

**Figure 39:** Molecular structures of tetrahydrotricyclopentadiene.

## 26.4 Chemical Properties of Tetrahydrotricyclopentadiene

### 26.4.1 Isomerization of Tetrahydrotricyclopentadiene

Isomerization of tetrahydrotricyclopentadiene, usually from the *endo*- to the *exo*-conformer, is part of the manufacturing process; therefore, it is discussed in a subsection of Section 25.1.

### 26.4.2 Thermal Decomposition of Tetrahydrotricyclopentadiene

The thermal decomposition properties of tetrahydrotricyclopentadiene were studied using DSC and TGA/DTG [314]. The pyrolysis products were C1–C5 alkynes, alkenes, and alkanes.

In a study of the thermal decomposition of tetrahydrotricyclopentadiene in a batch reactor at 658–698 K (385–425 °C), the reaction activation energy and pre-exponential coefficient were established as 248.5 kJ/mol and  $1.5 \times 10^{15} \text{ s}^{-1}$ , respectively [364]. A detailed analysis of the decomposition products indicated that THTCPD was first cracked into ethene,  $\text{C}_5$  (1,3-cyclopentadiene, cyclopentene, and cyclopentane), benzene, and  $\text{C}_{10}$  (JP-10 and its isomers), which then formed secondary products. The possible primary mechanism was the cleavage of the C–C bond of THTCPD, which produced diradicals that were further converted into monoradicals through intermolecular hydrogen abstraction. The monoradicals then generated primary products through  $\beta$ -scission, isomerization, and intermolecular hydrogen abstraction reactions. Possible secondary decomposition of primary products ( $\text{C}_{10}$  and  $\text{C}_5$  species) may form small molecules ( $\text{C}_1$ – $\text{C}_4$  species, methyl- and ethyl-cyclopentane, etc.), while some bimolecular reactions of  $\text{C}_5$  species may form naphthalene and 2,3-dihydro-4-methyl-1*H*-indene.

The high-pressure thermal decomposition of tetrahydrotricyclopentadiene (THTCPD) and binary high-density hydrocarbon fuels containing JP-10/THTCPD were investigated at 773–933 K (500–660 °C) and 4.0 MPa in an electrically heated tubular reactor [365]. The decomposition of THTCPD under high temperature, high pressure, and short residence time was conducted to analyze the effects of these variable on the product composition. The experimental results of JP-10/THTCPD pyrolysis showed that the THTCPD pyrolysis is easier than the thermal cracking of JP-10, and the addition of JP-10 can significantly promote the THTCPD pyrolysis, which was evidenced by the fact that THTCPD conversion increased up to 80% at 933 K (660 °C) when blended with 50% JP-10. The free radicals generated by the decomposition of THTCPD may help promote the decomposition of JP-10 via H-abstraction reactions.

## 27 Bicyclo[2.2.2]octane

Bicyclo[2.2.2]octane,  $\text{C}_8\text{H}_{14}$ , CAS RN [280-33-1], is a bridged cyclic hydrocarbon, but it has not found any applications as a fuel. It occurs as a contaminant in other polycyclic cycloaliphatic hydrocarbons. Other names for bicyclo[2.2.2]octane are 1,4-endoethylenecyclohexane and “cyclohexane, 1,4-*endo*-(1,2-ethanediyl)-.”

### 27.1 Physical Properties of Bicyclo[2.2.2]octane

Bicyclo[2.2.2]octane melts at 442–443 K (169–170 °C) and sublimes readily at room temperature. The vapor pressure of crystalline bicyclo[2.2.2]octane in the temperature range 323–363 K can be calculated from the equation

$$\log P = (2416.4/T) + 8.628$$

where  $P$  is the vapor pressure in mmHg and  $T$  is the temperature in kelvin [2]. The enthalpy of formation of bicyclo[2.2.2]octane vapor is  $-99.37 \pm 1.3$  kJ/mol ( $-23.75 \pm 0.30$  kcal/mol). The enthalpy of formation of solid bicyclo[2.2.2]octane is  $-147.1 \pm 0.4$  kJ/mol ( $-35.15 \pm 0.10$  kcal/mol). The heat of combustion of solid bicyclo[2.2.2]octane is  $5002 \pm 0.4$  kJ/mol ( $1195.49 \pm 0.10$  kcal/mol).

The enthalpy of sublimation in the range 323–363 K is  $46.36 \pm 0.8$  kJ/mol [139]. The enthalpy of sublimation at 298 K is  $47.76 \pm 0.8$  kJ/mol.

## 27.2 Molecular Structure of Bicyclo[2.2.2]octane

Bicyclo[2.2.2]octane is a homologue of bicyclo[2.2.1]heptane, norbornane. Bicyclo[2.2.2]octane is a cyclohexane with a  $-\text{CH}_2-\text{CH}_2-$  bridge from the 1 to the 4 position (Figures 40 and 41).

There are some heterocyclic amines with similar structures, with nitrogen atoms in the 1 position or both the 1 and 4 positions (triethylenediamine, DABCO). A bicyclo[3.3.0]octane also exists, which essentially consists of two cyclopentane rings sharing one side of the pentagons.

**Figure 40:** Molecular structure of bicyclo[2.2.2]octane.

**Figure 41:** Atom position numbering in molecular structure of bicyclo[2.2.2]octane.

## 28 Pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane

Pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane is one of the most unusual caged molecule structures, jokingly called a “bird cage.” It consists of three co-joined pentagons and one square. It is available only in small quantities and will not be used as a rocket propellant or jet fuel. It is shown here only to indicate that there are few limits to the complexity of these molecules, and initially nobody would have predicted that a complex molecule like *exo*-tetrahydrodicyclopentadiene would ever gain importance as the main ingredient of JP-10. So we continue to look at other complex molecules in the hope that there might be some more energetic ones and others that are easier to synthesize.

### 28.1 Synthesis of Pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane

Various laboratory methods have been developed for the synthesis of these unusual molecules [366, 367]. One of the synthesis methods starts with readily available ingredients, cyclopentadiene and *p*-quinone [368, 369].

The melting point of pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane (PCU) is 475.8 K, and the molar enthalpy of fusion is  $\Delta H_{\text{fus}}^\circ = 6.38 \pm 0.12 \text{ kJ/mol}$  [370]. The enthalpy of sublimation at 336.86 K was measured with a heat-conduction differential microcalorimeter as  $\Delta H_{\text{subl}}^\circ = 54.71 \pm 0.94 \text{ kJ/mol}$ . The weight-averaged value of the molar sublimation enthalpy at 298.15 K was  $\Delta H_{\text{subl}}^\circ = 55.85 \pm 1.00 \text{ kJ/mol}$ , based on  $\Delta C_p = 49 \text{ J K}^{-1} \text{ mol}^{-1}$ . The energy of combustion in oxygen was  $43332 \pm 31 \text{ J/g}$ , and the molar enthalpy of combustion was  $6345.2 \pm 4.8 \text{ kJ/mol}$ . The standard molar enthalpy of formation in the crystalline state was  $\Delta H_f^\circ(\text{cr}, 298.15 \text{ K}) = 15.8 \pm 4.9 \text{ kJ/mol}$ .

## 28.2 Molecular Structure of Pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]undecane

The molecular structure and energy content of PCU has been studied using DFT [371]. Based on the optimized geometrical parameters, the strain energy of the PCU molecule was calculated. The density of PCU was predicted using a Monte Carlo method based on the optimized results. The predicted IR frequencies and the NMR chemical shifts were calculated and were in good agreement with experimental results, and the calculated results were used to interpret the experimental spectra and to help determine the structure of PCU. The standard thermodynamic properties of PCU have been calculated by a statistical thermodynamic method.

## 29 Propellanes

Propellanes are polycyclic hydrocarbons with three rings that share a side of a three-, four-, five-, or six-membered ring. This symmetrical shape gives them the appearance of an airplane propeller, and that is where their name is derived from. The name *propellane* was proposed for compounds having three non-zero bridges and one zero bridge between a pair of bridgehead carbons. Although these strained-ring polycyclic hydrocarbons are predicted to be energetic molecules suitable as fuels in rockets or air-breathing engines, they are very difficult to synthesize, and they will most likely never find applications as rocket fuels. At this point, these compounds are mostly of theoretical interest. The shapes of some of these molecules have artistic appeal (“the synthetic chemist as artist”).

Some propellanes are shown above. From left to right are [1.1.1]propellane, [2.2.2]propellane, and 1,3-dehydroadamantane (a methylene-bridged derivative of [1.3.3]propellane).

The following sources in the literature offer additional information on propellanes, but for now this book cannot provide any more detail on the methods of preparation and physical properties of propellanes [372–379].

### 30 Caged Cycloaliphatic Hydrocarbons

Caged cycloaliphatic hydrocarbons are attractive rocket fuels because they have high densities, which is apparent when comparing 3D cages with flat building blocks that make up their flat sides (Figure 42).

| MONOCYCLE                                                                         | DENSITY, g/cm <sup>3</sup> | CAGED                                                                             | DENSITY, g/cm <sup>3</sup> |
|-----------------------------------------------------------------------------------|----------------------------|-----------------------------------------------------------------------------------|----------------------------|
|  | 0.70                       |  | 1.28                       |
|  | 0.74                       |  | 1.45                       |
|  | 0.78                       |  | 1.07                       |

**Figure 42:** Caged hydrocarbons with high densities.

Bicyclic and cage compounds have high heats of combustion and can be used as fuels. A literature survey of the field of bicyclic and cage compounds was conducted with the objective of identifying those types of compounds with unusual physical and chemical stability [380]. There are many caged alicyclic and heterocyclic compounds that are potentially useful as rocket propellants [381, 382].

Calculations of thermodynamic properties (heat capacities, standard entropies, and enthalpies of formation) of some caged hydrocarbons of the general formula  $C_nH_n$  in the ideal-gas state were performed for tetrahedrane  $C_4H_4$ , triprismane  $C_6H_6$ , cubane  $C_8H_8$ , pentaprismane  $C_{10}H_{10}$ , hexaprismane  $C_{12}H_{12}$ , truncated tetrahedrane  $C_{12}H_{12}$ , heptaprismane  $C_{14}H_{14}$ , octaprismane  $C_{16}H_{16}$ , dodecahedrane  $C_{20}H_{20}$ , truncated octahedrane  $C_{24}H_{24}$ , and truncated cubane  $C_{24}H_{24}$  [383].

The synthetic routes to the synthesis of prismanes are summarized in [384]. Some of the more exotic caged hydrocarbons, promising fuel candidates heptacyclo-[6.6.0.0<sup>2,5</sup>.0<sup>3,13</sup>.0<sup>4,11</sup>.0<sup>5,9</sup>.0<sup>10,14</sup>]tetradecane (HCTD) and pentacyclo[5.4.0.0<sup>2,6</sup>.0<sup>3,10</sup>.0<sup>5,9</sup>]-undecane (PCUD), were synthesized and evaluated as ramjet fuels [385]. The density of HCTD is 1.26 g/cm<sup>3</sup>, and the density of PCUD is 1.23 g/cm<sup>3</sup>. Some of these caged and bridged structures are related to homocubanes [386].

Reductive dimerization of methylated pentacycloundecan-8-ones gave mixtures of methylated pentacycloundecane (PCU) alkene dimers [387].

Thermal properties of four high-energy-density PCU-derived hydrocarbons were investigated [388]. All of these fuels were stable and non-volatile at room temperature and pressure. Two fuels were solid, and the third was a viscous liquid. The PCU alkene dimer,  $C_{22}H_{24}$ , was a mixture of isomers with a high enthalpy of formation (+408 kJ/mol), high density (1.2–1.3 g/cm<sup>3</sup>) and a melting point of 451–452 K (178–179 °C). The calculated heat of combustion was 11900 kJ/mol. The methylated PCU alkene dimer,  $C_{22}H_{28}$ , was a mixture of up to 64 isomers. The methylated fuel was a wax-like material with a melting point of 328 K (55 °C). In contrast to the base PCU alkene dimer, the methylated PCU alkene dimer was soluble in kerosene. The spirocyclic alkene dimer,  $C_{22}H_{26}$ , was a mixture of two isomers in the form of a powder with a melting point of 432 K (159 °C). Methylenecyclopropane,  $C_{18}H_{22}$ , a mixture of two isomers, was semi-solid at room temperature and formed a viscous oil.

### 31 Cubane

Cubane, pentacyclo[4.2.0.0<sup>2,5</sup>.0<sup>3,8</sup>.0<sup>4,7</sup>]octane, C<sub>8</sub>H<sub>8</sub>, CAS RN [277-10-1], is a highly energetic hydrocarbon and the parent compound of a group of high-energy materials including tetranitrocubane and octanitrocubane. It was believed for a long time that a molecule like cubane would not be stable and might be impossible to synthesize, but cubane has a surprising stability. Cubane is now the parent molecule of a large number of energetic compounds that are of interest as rocket propellants and explosives [389].

### 31.1 Preparation of Cubane

The first synthesis of cubane in a nine-step reaction was reported in 1964 [390, 391]. Similar methods are available for the synthesis of methylcubane [392]. Methylcubane melts at 307 K (34 °C) and sublimates at 310 K (37 °C). There are now several methods for cubane synthesis [393, 394]. One new method allows the synthesis of cubane in a four-step reaction [395].

Cubane and methylcubane are of interest as high-density fuels and as parent molecules for energetic compounds. The most readily accessible starting material for the synthesis of energetic cubanes is cubane-1,4-dicarboxylic acid, which can be prepared in a seven-step process [396]. Functional group transformations of this diacid have yielded energetic derivatives such as 1,4-dinitrocubane, 1,4-di(hydrazomethyl)-cubane, and 1,4-di(*N*-nitroamino)cubane. The diacid has been converted to both 1,2,4,7- and 1,3,5,7-cubane-tetracarboxylic acids, from which the energetic molecules 1,2,4,7-cubane-tetraammonium tetraperchlorate and 1,3,5,7-tetranitrocubane have been synthesized.

### 31.2 Physical Properties of Cubane

Cubane is a solid at room temperature and has a molecular mass of 104.15 g/mol and a density of 1.29 g/cm<sup>3</sup> (remarkable for a hydrocarbon). It melts at 406.6 K (133.5 °C = 272.3 °F) and boils at 434.8 K (161.6 °C = 322.9 °F).

Cubane crystallizes as small rhombs (*O<sub>h</sub>* point group) and is one of the densest hydrocarbons known. The measured enthalpy of formation of solid cubane is +620 kJ/mol (+148 kcal/mol). This is a notably high value and quite unlike that of common hydrocarbons. Most of these saturated hydrocarbons have negative heats of formation.

#### 31.2.1 Lattice Dynamics of Cubane Crystals

Solid cubane, which is composed of weakly interacting cubic molecules, exhibits many unusual and interesting properties, such as a very large coefficient of thermal expansion and a first-order phase transition at 394 K from an orientationally ordered phase of *R*3 symmetry to a non-cubic disordered phase of the same symmetry with a volume expansion of 5.4%, among the largest ever observed [397]. A study of the lattice dynamics of solid cubane within the quasi-harmonic and rigid-molecule approximation tried to explain some of these unusual dynamical properties. The experimental melting temperature of cubane is 405 K, indicating a strong crystal lattice.

### 31.2.2 Thermodynamic Properties of Cubane

The measured enthalpy of formation of solid cubane is  $+620 \text{ kJ/mol}$  ( $+148 \text{ kcal/mol}$ ). This is a notably high value and is quite unlike that of common hydrocarbons. Most of these more common saturated hydrocarbons have negative heats of formation.

The sublimation enthalpy of cubane was measured by combining the vaporization enthalpy at  $298.15 \text{ K}$  with the sum of the fusion enthalpy measured at  $405 \text{ K}$  and a solid-solid phase transition that occurs at  $394 \text{ K}$  [398]. The fusion and solid-solid phase transitions were measured previously. A sublimation enthalpy value of  $55.2 \pm 2.0 \text{ kJ/mol}$  at  $298.15 \text{ K}$  was obtained. This value compared quite favorably with the value obtained by comparing the sublimation enthalpy of similar substances as a function of their molar masses, but it is different from earlier measurements. The heat of combustion for cubane is  $46.5 \text{ MJ/kg}$ , which corresponds to an enthalpy of formation of  $+602 \text{ kJ/mol} = +144 \text{ kcal/mol}$  [399, 400].

Three commonly used density functional methods for computing heats of formation for cubane vapor were compared [401]. Heats of formation were computed from the total energies of this strained hydrocarbon and building elements (carbon and hydrogen molecule), with the experimental carbon enthalpy of formation given ( $+710.9 \text{ kJ/mol} = +169.9 \text{ kcal/mol}$ ). It was demonstrated that the complete basis-set *ab initio* method computes heats of formation that are very close to the experimental, as well as G2, values. Hybrid DFT computes almost identical values and was recommended as the method of choice for computing heats of formation, while local spin density approximation generates energies that are a few hundred  $\text{kcal/mol}$  different from the experimental value and should be avoided for these calculations. For cubane vapor, there is an experimental enthalpy of formation of  $+622.2 \pm 4.2 \text{ kJ/mol} = +148.7 \pm 1 \text{ kcal/mol}$  at  $298 \text{ K}$ . Again, the estimated energy agreed well with this value. In fact, it differed by only  $3.3 \text{ kJ/mol} = 0.8 \text{ kcal/mol}$ . The computed cubane enthalpy of formation deviated slightly more from this value. Similarly, as it was in the case of tetrahydronaphthalene, the enthalpy of formation for cubane was substantially different (for more than  $1255 \text{ kJ/mol} = 300 \text{ kcal/mol}$ ) than estimated from the experimental data.

The heat of combustion of solid cubane is  $4837 \text{ kJ/mol}$  ( $1156 \text{ kcal/mol}$ ), which translates into an enthalpy of formation of  $+541.8 \pm 3.3 \text{ kJ/mol}$  ( $+129.5 \pm 0.8 \text{ kcal/mol}$ ) for the solid and  $+622.2 \pm 4.1 \text{ kJ/mol}$  ( $+148.7 \pm 1.0 \text{ kcal/mol}$ ) for the vapor [402]. The strain energy of  $157 \text{ kcal/mol}$  distributed over the six faces of the cube gives  $26.2 \text{ kcal/mol}$  per cube face, which is very similar to that of cyclobutane at  $26 \text{ kcal/mol}$ . The unusually high enthalpy of formation of cubane and many of its derivatives can be explained by strain energy [52]. The term strain energy should be considered relative to a theoretical unstrained state of the molecule. The strain energy can be calculated from the difference between the experimentally determined enthalpy of formation and the enthalpy of formation predicted from additive behavior of unstrained bonds:

$$\text{Strain energy} = \Delta H_{\text{f,exp.}} - \Delta H_{\text{f,calc.}}$$

### 31.2.3 Molecular Structure of Cubane

The molecular structure of cubane shows that the molecule is highly stressed, because on eight carbon atoms the bonds are bent away from the stress-free tetrahedron bond angle of  $109.45^\circ$  to those of the corners of a cube with  $90^\circ$  angles (Figure 43).

**Figure 43:** Molecular structure of cubane.

Cubane is named appropriately because its skeleton is in the shape of a cube. At each corner of this cube is a carbon atom (carrying a hydrogen) bound to three identical neighboring carbons. The internuclear  $\angle CCC$  angles are  $90^\circ$ , bent far off from the standard  $109.5^\circ$  typical of tetravalent,  $sp^3$ -hybridized carbons like those in methane. This departure from normal bond orientation is energetically expensive. Cubane is strained by about  $695 \text{ kJ/mol}$ , corresponding to a substantial weakening of its bonds. The large bond angle deformations in cubane make it a treasure of stored energy. Each strained bond is like the spring in a set mousetrap. It was once thought that cubane would be impossible to synthesize or stabilize. Neither concern proved to be the case. The cubane system and cubane itself were first synthesized in 1964 at the University of Chicago.

Bicubyl consists of two cubes connected by a single C—C bond. Bicubyl has a density of  $1.336 \text{ g/cm}^3$ , significantly higher than cubane ( $1.29 \text{ g/cm}^3$ ). Other polycubyls are known and together make an interesting set of stable rigid chains to which each cubyl link adds  $0.42 \text{ nm}$  to the length of the chain. Nitro derivatives of these polycubyls are not yet known. Even if they were, they would be prohibitively expensive.

### 31.2.3.1 Computational Chemistry for Polycyclic Strained-Ring Caged Energetic Materials

Compounds containing carbon-based (no hetero atoms) cage structures have highly strained molecular structures and have become the subject of practical interest in recent decades because they possess high enthalpy of formation. *Ab initio* molecular modeling calculations have been performed for 28 carbon-cage structures with the aim of identifying the best candidates for future synthesis work in order to improve propellant compositions [403]. DFT was employed for the geometric optimization of the proposed molecules. Calculated heats of formation and densities of the compounds have been used from the optimized structures to compute their specific impulses and density-specific impulses in various configurations (solid and liquid rocket propellants). Detonation properties of air/fuel mixtures of these compounds have been predicted.

### 31.2.3.2 Computational Chemistry for Tetrahedrane

Three commonly used density functional methods for computing heats of formation for tetrahedrane were compared [401]. Enthalpies of formation were computed from the total energies of tetrahedrane. The enthalpy of formation of tetrahedrane vapor was estimated, through homodesmotic reactions, to be  $+535 \pm 4$  kJ/mol ( $+127.9 \pm 1.0$  kcal/mol) at 298 K. The same approach was used for the DFT evaluation of the tetrahedrane enthalpy of formation. The values computed with three different basis sets were +600, +523, and +610 kJ/mol (+143.4, +125.1, and +145.7 kcal/mol), respectively.

Tight-binding molecular dynamics simulations were carried out to analyze the thermal stability of the  $C_4H_4$  tetrahedrane molecule over a wide temperature range from 400 to 1000 K [404]. The temperature dependence of the  $C_4H_4$  lifetime  $\tau$  was related to the Arrhenius law. The height of the minimum energy barrier preventing the tetrahedrane decomposition was found to be 0.46 eV. Possible channels and final products of the tetrahedrane decay were identified.

### 31.2.3.3 Computational Chemistry for Prismanes

The group of prismanes includes the polyhedral hydrocarbons tetrahedrane, cubane (tetraprismane), and dodecahedrane. An *ab initio* computational study was performed to obtain the bond energies and geometries of the lower prismanes [405]. See also [406].

### 31.2.3.4 Computational Chemistry of Cubane Structures

The enthalpy of formation of cubane,  $C_8H_8$ , pentacyclo[4.2.0.0<sup>2,5</sup>.0<sup>3,8</sup>.0<sup>4,7</sup>]octane, CAS RN [277-10-1], can be derived from the properties of its fragments. A composite molecular orbital method was used to calculate standard enthalpies of formation and hydrogenation ( $\Delta H_f^{298}{}_0$ ,  $\Delta H_{hyd}^{298}{}_0$ ) of a series of compounds obtained from cubane by successively breaking one C—C single bond at a time [407]. The enthalpy of

isomerization of each cubane derivative was compared to the corresponding isomer in the sequence obtained by stepwise hydrogenation of cycloocta-1,3,5,7-tetraene to cyclooctane [401].

The gas-phase enthalpy of formation of cubane ( $603.4 \pm 4$  kJ/mol) was calculated using an explicitly correlated composite method [408]. The results obtained for cubane, together with the experimental value for the enthalpy of sublimation,  $54.8 \pm 2.0$  kJ/mol, led to a value of  $+548.6 \pm 4.5$  kJ/mol for the solid-phase enthalpy of formation of cubane. This value was only 6.8 kJ/mol higher than the 50-year-old original calorimetric result. The carbon-hydrogen bond dissociation enthalpy of cubane is  $438.4 \pm 4$  kJ/mol. The strain energy of cubane (667.2 kJ/mol) and cubyl radical (689.4 kJ/mol) were independently estimated via quasi-homodesmotic reactions.

### 31.3 Other Information on Cubanes

Cubanes with methylene bridges across the sides are called homocubanes, with *bis* and *tris* indicating the number of methylene bridges. It is hard enough to synthesize cubane and cubane derivatives and test them as energetic materials, but making homocubanes is even more difficult, and it is very unlikely that they could ever be used as rocket propellants. These molecules are mostly of theoretical interest [386]. An alternative name for homocubane is pentacyclo[4.3.0.0<sup>2,5</sup>.0<sup>2,8</sup>.0<sup>4,7</sup>]nonane [409].

Homocubane is a potential support backbone for a family of high-energy-density materials [410]. Six polynitro and polyazido diesters of homocubane-2,4-dicarboxylic acid were synthesized as possible energetic plasticizers. 2,4-dicyano and dinitro homocubanes were synthesized as models for more highly substituted homocubanes. Dinitrate and diperchlorate salts of 2,4-diaminohomocubane were prepared via proper ion exchange resins. The energy content of bishomocubane molecules can be increased by attaching tetrazole rings [411]. A variety of cubane derivatives was synthesized in a search for more energetic fuels, including 1,4-diazidomethylcubane and 1,4-dihydroxymethylcubane [202].

### 31.4 Chemical Properties of Cubane

Interest in cubane chemistry was triggered by potential applications of the molecule and its derivatives to the production of high-energy fuels and propellants [389]. Once initial substitution of hydrogen in cubane by amino groups or iodine is achieved, this will open new paths for the synthesis of polysubstituted energetic cubane derivatives [412, 413]. New cubane derivatives have been prepared by developing new methodology for direct substitution on the cubane nucleus [414].

### 31.5 Thermal Decomposition of Cubane

The decomposition chemistry of cubane and other high-energy-density fuels was investigated by flow tube mass spectrometry [415]. Pyrolysis reactions of cubane and methylcubane were studied in a micro-flow tube reactor from room temperature to 1000 K [416]. The composition of the flow tube eluent was analyzed by chemical ionization in a tandem guided beam mass spectrometer. It was found that cubane and methylcubane have nearly identical breakdown temperature dependence, suggesting that methyl functionalization has minimal effect on the stability of cubane cage bonds. There is, however, a substantial effect of the methyl group on product branching, resulting in more stable isomers at intermediate temperatures and a propensity to eliminate fragments containing the methyl group at high temperatures.

The reasons for the anomalously high thermal stability of cubane  $C_8H_8$  and the mechanisms of its decomposition were studied by numerically simulating the dynamics of this metastable cluster at  $T = 1050 - 2000$  K using a tight-binding potential method [417]. The decomposition activation energy was found from the temperature dependence of the cubane lifetime obtained from the numerical experiment. The activation energy is fairly high,  $E_a = 1.9 \pm 0.1$  eV. The decomposition products are either  $C_6H_6$  and  $C_2H_2$  molecules or the isomer  $C_8H_8$  with a lower energy. The thermodynamic instability of cubane, due to having a positive enthalpy of formation, is not accompanied by kinetic instability. Cubane and most of its derivatives are amazingly stable. The energy of activation for thermal decomposition of cubane in the gas phase is very large, about 180 kJ/mol at 503–533 K (230–260 °C), so the molecule decomposes only slowly at such temperatures. The reason for this is that there are no kinetically viable paths along which cubane can rearrange thermally.

A detailed chemical kinetics mechanism was developed for the decomposition of cubane [418]. Quantum mechanics-based *ab initio* calculations have been carried out to elucidate the various chemical pathways that lead to the formation of previously known product species from cubane. Optimized structures of ground states and transition states appearing in the chemical reaction scheme were obtained by using various levels of theory. Minimum energy paths were traced for each elementary reaction. The mechanism thus obtained, along with the computed rate parameters and thermodynamic data, was used in a flow reactor model to simulate a flow reactor experiment that was carried out previously by others. Comparison of the simulation and experimental results validated the formulated reaction mechanism and provided valuable insights into the chemical decomposition behavior of cubane.

## 32 Adamantane

Adamantane, also known as  $C_{10}H_{16}$ , tricyclo[3.3.1.1<sup>2,6</sup>]decane, CAS RN [281-23-2], contains 12.27 mass-% hydrogen and has a molecular mass of 164.29 g/mol.

Adamantane is a colorless, crystalline chemical compound with a camphor-like odor. It is a cycloalkane and the simplest diamondoid and is related to many compounds that are of interest as air-breathing engine fuels or rocket propellants [419]. Attaching explosophoric groups leads to nitroadamantane or difluoroaminoadamantane, potential high-energy-density materials. Adamantane and a variety of alkyl-substituted adamantanes (“diamondoid hydrocarbons”) occur naturally in some deep petroleum reservoirs. Because of their ease of sublimation, they are carried to the surface with natural gas from those underground formations.

### 32.1 Preparation of Adamantane

A simple two-step reaction allows the synthesis of adamantane from the readily available dicyclopentadiene by first reducing it to tetrahydrodicyclopentadiene and then refluxing the tetrahydrodicyclopentadiene for 10 h over an  $AlCl_3$  catalyst [420]. Strong sulfuric acid catalyzes isomerization of trimethylenenorbornane = tetrahydrodicyclopentadiene to adamantane [421].

As part of a study of the synthesis of adamantane on zeolite catalysts and the reaction conditions, it was found that Ni(3–5% Ni)/USY catalyst exhibited a higher activity and good selectivity for adamantane preparation [422]. The best reaction conditions were temperature 523–553 K (250–280 °C), catalyst content 25–28%, and hydrogen pressure 10–15 MPa. It was found that the presence of a little dry HCl increased the yield of adamantane.

Adamantane can be synthesized in a batch reactor system under hydrogen using *endo*-tetrahydrodicyclopentadiene (*endo*-TCD) as feedstock and solid super-acid  $ZrO_2-SO_4$  (SZ)-loaded REY, USY, or Si-MCM-41 molecular sieves as isomerizing catalysts [423]. Loading  $ZrO_2-SO_4$  on the surface of a molecular sieve increased the yield of adamantane. The effects of reaction temperature, hydrogen pressure, content of the surface-loaded  $ZrO_2$ , and types of molecular sieves on synthesis of adamantane were investigated. The results showed that higher temperature 540 K (270 °C) will increase the yield of hydrocracking (by-products), which led to a decrease in adamantane yield. The highest yield of adamantane (22.77%) was obtained by using (SZ(20%))/REY as isomerizing catalyst under the following conditions: catalyst/reactant mass ratio 0.625, reaction temperature 523 K (250 °C), hydrogen pressure 1.5 MPa, and reaction time 3 h. The total selectivity of adamantane conversion was 95%.

The catalytic activity of 12-tungstophosphoric acid-supported PW/C catalysts in the isomerization of *endo*-tetrahydrodicyclopentadiene (*endo*-TCD) to adamantane was investigated in a batch reactor [424]. Under optimum conditions, the PW loading was 30% by weight, the reaction temperature was 413 K (240 °C), the reaction time was 3 h, the mass ratio of catalyst and material was 0.6:1.0, the initial pressure was 1.1 MPa, and the molar ratio of cyclohexane solvent and *endo*-TCD was 5:1. The maximum yield of adamantane was up to 21.6%.

Adamantane can be made by isomerization of *exo*-tetrahydrodicyclopentadiene to adamantane using an acidity-adjustable chloroaluminate ionic liquid [283]. The zeolite catalytic method is considered to be the most typical and the more active method for the synthesis of adamantane and is likely to become the preferred replacement for the conventional  $\text{AlCl}_3$  method on an industrial scale [425]. Some adamantane is obtained as an unwanted by-product during the production of *exo*-tetrahydrodicyclopentadiene, the main ingredient of JP-10.

## 32.2 Physical Properties of Adamantane

### 32.2.1 Melting Point of Adamantane

The melting point of adamantane is 542.7–543.9 K (269.6–270.8 °C) in a sealed vial. At 540 K (270 °C), the melting point of adamantane is much higher than that of other hydrocarbons with the same molecular weight, such as camphene (318 K = 45 °C) or limonene (199 K = –74 °C). Other sources reported the melting point of adamantane as 552 K.

### 32.2.2 Vapor Pressure of Adamantane

Adamantane sublimates readily. The vapor pressure of crystalline adamantane in the temperature range 366–443 K can be calculated from the equation

$$\log P = (-2746.8/T) + 8.617$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin [2]. A similar equation applies to a wider temperature range from 313 to 443 K:

$$\log P = (-4054.4/T) + 29.220 - 6.666 \log T$$

The enthalpy of formation of solid adamantane is  $-128.2 \pm 4.1$  kJ/mol ( $-30.65 \pm 0.98$  kcal/mol) [2]. The heat of combustion of adamantane is  $6033 \pm 3$  kJ/mol ( $1441.95 \pm 0.68$  kcal/mol).

Other sources [158] gave the following equations for the vapor pressure of adamantane, the first for the solid in the temperature range 483–543 K and the second

one for the liquid at temperatures above 543 K

$$\ln p = A - \frac{B}{T} = 18.18 - \frac{6570}{T} \quad 483 < T < 543 \text{ K}$$

$$\ln p = A - \frac{B}{T} = 14.75 - \frac{4670}{T} \quad T > 543 \text{ K}$$

where  $p$  is the pressure in kPa and  $T$  is the temperature in kelvin.

### 32.2.3 Optical Properties of Adamantane

#### 32.2.3.1 Infrared Spectrum of Adamantane

The IR spectrum of adamantane is shown in Figure 44. Due to the high symmetry of the molecule, the number of absorption bands is very small.

**Figure 44:** Infrared spectrum of adamantane. (Reprinted and modified with permission from [426].)

#### 32.2.4 Molecular Structure of Adamantane

Adamantane molecules consist of four connected cyclohexane rings arranged in the “chair” configuration. Adamantane is unique in that it is both rigid and virtually stress free and is highly symmetrical. A boat-shaped configuration can also exist. Adamantane is the most stable among all the isomers with the empirical formula  $C_{10}H_{16}$ , which include the somewhat similar twistane. The spatial arrangement of carbon atoms in adamantane molecule is the same as in the diamond crystal, which is where the name adamantane is derived from. The molecular structure of adamantane is illustrated in Figure 45.

**Figure 45:** Molecular structure of adamantane.

The molecular and crystal structure of adamantane was examined using XRD, FTIR, MS, NMR, enhanced MS, differential ion mobility spectrometry, Raman, and DSC, revealing phase transitions of adamantane at different temperature or pressure conditions [427]. The molecular parameters were deduced by electron diffraction and X-ray crystallography. The carbon-carbon bond length is 1.54 Å and is almost identical to that of diamond, and the carbon-hydrogen distance is 1.112 Å. Adamantane crystallizes in a face-centered cubic structure (space group  $Fm\bar{3}m$ ,  $a = 9.426 \pm 0.008$  Å,  $Z = 4$ ) containing orientationally disordered adamantane molecules. This structure transforms into an ordered body-centered tetragonal phase ( $a = 6.641$  Å,  $c = 8.875$  Å) with  $Z = 2$  either upon cooling to 208 K or pressurizing to above 0.5 GPa.

### 32.2.5 Thermodynamic Properties of Adamantane

#### 32.2.5.1 Heat Capacity of Adamantane

The constant-pressure heat capacity of crystalline adamantane at 298 K is  $189.74 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $45.3 \text{ cal mol}^{-1} \text{ }^{\circ}\text{C}^{-1}$ ). The heat capacity of adamantane vapor at 298 K is  $148.91 \text{ J mol}^{-1} \text{ K}^{-1}$  ( $35.6 \text{ cal mol}^{-1} \text{ }^{\circ}\text{C}^{-1}$ ).

#### 32.2.5.2 Enthalpy of Formation of Adamantane

Based on a measured heat of combustion of solid adamantane of  $6033 \pm 3 \text{ kJ/mol}$  ( $1441.95 \pm 0.68 \text{ kcal/mol}$ ), an enthalpy of formation for solid adamantane was calculated as  $-188.7 \pm 2.8 \text{ kJ/mol}$  ( $-45.10 \pm 0.68 \text{ kcal/mol}$ ) [2]. The enthalpy of formation of adamantane vapor is  $-132.9 \pm 1.3 \text{ kJ/mol}$  ( $-31.76 \pm 0.32 \text{ kcal/mol}$ ). The enthalpy of formation of crystalline adamantane is  $-192.5 \pm 0.4 \text{ kJ/mol}$  ( $-46.02 \pm 0.09 \text{ kcal/mol}$ ) [428].

The standard enthalpy of combustion of adamantane is  $\Delta H_c = 6033 \pm 3 \text{ kJ/mol}$  ( $1442.01 \pm 0.78 \text{ kcal/mol}$ ), which yields a standard enthalpy of formation of  $\Delta H_f^{298} = -188.4 \pm 3.3 \text{ kJ/mol}$  ( $-45.02 \pm 0.79 \text{ kcal/mol}$ ) [429].

#### 32.2.5.3 Enthalpy of Fusion of Adamantane

The enthalpy of fusion of adamantane is  $13.8 \text{ kJ/mol}$  ( $3.3 \text{ kcal/mol}$ ) [430].

#### 32.2.5.4 Enthalpy of Sublimation of Adamantane

The heat of sublimation of adamantane is  $59.7 \text{ kJ/mol}$  ( $14.26 \text{ kcal/mol}$ ). Other sources reported the enthalpy of sublimation of adamantane at 308 K as  $58.3 \text{ kJ/mol}$  ( $13.93 \text{ kcal/mol}$ ) [430].

The enthalpy of sublimation of adamantane is  $59.1 \text{ kJ/mol}$  at 298 K and  $58.3 \text{ kJ/mol}$  at 308 K [139]. Other sources gave an enthalpy of vaporization of  $52.6 \text{ kJ/mol}$  or  $48.5 \pm 3.8 \text{ kJ/mol}$  at 298 K [158].

#### 32.2.5.5 Heat of Combustion of Adamantane

The heat of combustion of adamantane is  $6029 \pm 4 \text{ kJ/mol}$  ( $1441 \pm 1 \text{ kcal/mol}$ ) [428].

### 32.3 Alkyladamantanes

Alkyladamantanes have the advantage over adamantane in that they are liquids at room temperature and thus are easier to use as rocket fuels.

The most thoroughly investigated alkyladamantane is 1,3-dimethyladamantane, 1,3-DMA, CAS RN [702-79-4]. The boiling point of 1,3-dimethyladamantane is 476.4 K. The enthalpy of vaporization of 1,3-dimethyladamantane was reported as  $49.37 \pm 0.33$  kJ/mol [431] or  $51.2 \pm 0.5$  kJ/mol [158].

The thermal stability of 1,3-dimethyladamantane was investigated under different conditions because it is a candidate for high-energy-density hydrocarbon fuels [432]. The thermal decomposition kinetics in a batch reactor between 693 and 743 K proceeded with rate constants ranging from  $4 \times 10^{-7} \text{ s}^{-1}$  at 693 K to  $35 \times 10^{-7} \text{ s}^{-1}$  at 743 K, along with the Arrhenius parameters of  $A = 2.39 \times 10^7 \text{ s}^{-1}$  and activation energy  $E_a = 183$  kJ/mol. The rate constants for the thermal decomposition of 1,3-DMA were smaller than those of some typical model fuels such as decalin, propylcyclohexane, butylcyclohexane, and *n*-dodecane, demonstrating that the thermal stability of 1,3-DMA is satisfactory. On the basis of component analysis, a hypothetical mechanism of thermal decomposition of 1,3-DMA was proposed to explain the product distribution. It was shown that the different products are mainly obtained through a combination of isomerization, hydrogen transfer,  $\beta$ -scission, and dehydrogenation.

The heat capacities of the crystalline and liquid phases of 1,3-dimethyladamantane and 1-ethyladamantane have been measured over the temperature range 8 to 373 K [433]. 1,3-dimethyladamantane was found to exist in two crystalline phases; 1-ethyladamantane exists in only one crystalline phase.

### 32.4 Natural Occurrence of Adamantane Derivatives (Diamondoids)

Naturally occurring diamondoids are the most stable remnants of petroleum degradation over geologic time. These compounds have survived the severe geologic time/temperature/pressure conditions at great depths where most other hydrocarbons, except methane, are destroyed by either thermal cracking and/or thermochemical reduction. Some geochemists have tried to explain their presence as the result of acid-catalyzed rearrangements of alicyclic hydrocarbons in petroleum. Diamondoids are known to occur as trace components in some crude oils, but they are also found subliming in natural gas. There have been only two reported occurrences of diamondoids in natural gas reservoirs worldwide. Diamondoids are predominantly adamantane, diamantane, triamantane, and their methyl- and ethyl-substituted counterparts. For the most part, alkyl side chains longer than propyl have been cracked off in thermal reactions over the past millions of years. Analysis of these natural gas condensates has revealed several dozen diamondoids with structures similar to that of adamantane [146]. Mixtures of diamondoids have been proposed as high-density fuels under the

name Mobildym Fuels RF. The energy released per unit volume of the RF-1, RF-2, and RF-3 fuels in a ramjet combustor was found to be significantly greater than that of JP-10 over a wide range of air/fuel equivalence ratios. Efforts have started for synthesizing fuels with properties similar to those of diamondoid fuels but beginning with readily available feedstocks instead – the same as those used for the production of JP-10, except continuing the dimerization reaction by building multi-ringed caged molecules by oligomerization of DCPD to C15+ molecules.

### 33 Dodecahedrane

Dodecahedrane, also known as pentagonal dodecahedrane, undecacyclo [9.9.0.0<sup>2,9</sup>.0<sup>3,7</sup>.0<sup>4,20</sup>.0<sup>5,18</sup>.0<sup>6,16</sup>.0<sup>8,15</sup>.0<sup>10,14</sup>.0<sup>12,19</sup>.0<sup>13,17</sup>]dodecane, C<sub>20</sub>H<sub>20</sub>, CAS RN [4493-23-6], is a platonic hydrocarbon that has been the subject of many experimental and theoretical studies. It consists of 12 pentagons linked in a spherical structure. A platonic hydrocarbon is a hydrocarbon (molecule) whose structure matches one of the five platonic solids, with carbon atoms replacing its vertices, carbon–carbon bonds replacing its edges, and hydrogen atoms as needed on the apex points. The synthesis of dodecahedrane, a 20-step reaction, makes this compound very difficult to obtain, and it will never be used as a rocket propellant. It would be interesting to see how many nitro groups or amino groups can be attached to the carbon skeleton to make a new oxidizer or fuel.

#### 33.1 Physical Properties of Dodecahedrane

The physical properties of dodecahedrane are listed in Table 33.

**Table 33:** Physical properties of dodecahedrane.

| Property                                                                 | SI units                | Other units        | References |
|--------------------------------------------------------------------------|-------------------------|--------------------|------------|
| Molecular mass                                                           | 260.3728 g/mol          | 3.8406 mol/kg      |            |
| Melting point                                                            | 703 ± 10 K              | 430 ± 10 °C        |            |
| Density                                                                  | 1.448 g/cm <sup>3</sup> | —                  |            |
| Enthalpy of formation (estimated)                                        | +79.1 kJ/mol            | +18.9 kcal/mol     | [434]      |
| Enthalpy of formation, vapor, computed                                   | +76.1 kJ/mol            | +18.2 kcal/mol     | [120]      |
| Enthalpy of formation, vapor (from heat of combustion of dimethyl ester) | +93.7 kJ/mol            | +22.4 ± 1 kcal/mol | [39]       |

### 33.1.1 Molecular Structure of Dodecahedrane

The molecular structure of dodecahedrane is illustrated in Figure 46. Each apex carries one hydrogen atom.

Figure 46: Molecular structure of dodecahedrane.

### 33.1.2 Thermodynamic Properties of Dodecahedrane

*Ab initio* molecular orbital calculations to predict accurate geometries and enthalpies of formation have been applied to cyclohexane, cubane, adamantane, and dodecahedrane [435]. Good agreement with experimental data was obtained for geometries in all cases. In the 6-31G basis set, enthalpies of formation of cyclohexane, adamantane, and cubane were in error by 0.5, 2.1, and 9.9 kcal/mol, respectively. For dodecahedrane, the enthalpy of formation was predicted to be  $-20.9$  kJ/mol ( $-5.0$  kcal/mol). This number had to be revised later when a different computational method was used. The enthalpy of formation of dodecahedrane was estimated from the difference of *ab initio* energies of dodecahedrane and pagodane, as well as from two homodesmotic reactions [434]. The results,  $+79.1$ ,  $+73.2$ , and  $+69.9$  kJ/mol ( $+18.9$ ,  $+17.5$ , and  $+16.7$  kcal/mol), depending on the method of calculation, were in modest agreement with a value estimated by others,  $+93.7 \pm 4.1$  kJ/mol ( $+22.4 \pm 1$  kcal/mol).

## 33.2 Chemical Properties of Dodecahedrane

It would be of interest to attach explosophoric groups to the dodecahedrane sphere, similar to what has been done with cubane, where substitution of eight hydrogens by nitro groups resulted in the formation of octanitrocubane. The other possibility with dodecahedrane is to insert small molecules into the cavity formed by the sphere.

## 34 Buckminsterfullerene C<sub>60</sub>

Fullerene also known as C<sub>60</sub>, (C<sub>60</sub>-Ih)[5,6]fullerene, Buckminsterfullerene, Buckyball, [60]fullerene, CAS RN [99685-96-8], has unique properties that would make it and its derivatives useful as propellant ingredients. Of course, these compounds are solids and not liquids, so their use would be restricted to solid propellants [436].

# Dimethylhydrazines

## Dimethylhydrazines

*Encyclopedia of Liquid Fuels* contains six chapters that discuss hydronitrogen compounds and four chapters that discuss hydrazines. The chapter on hydrazine deals with the parent compound, which is an inorganic compound. The chapter regarding alkylhydrazines discusses alkylhydrazines compounds but not methylhydrazine or dimethylhydrazines. This is followed by a chapter focused on methylhydrazine, and finally, a chapter regarding dimethylhydrazines, which is the chapter at hand.

There are two dimethylhydrazines, which will be the focus of this chapter. They differ in location regarding where the two methyl groups are attached to the two nitrogen atoms. The unsymmetrical dimethylhydrazine (UDMH), where both methyl groups are attached to the same nitrogen atom, is of more importance than symmetrical dimethylhydrazine, where two methyl groups are attached to different nitrogen atoms. UDMH is widely used as rocket fuel. In contrast, symmetrical dimethylhydrazine (SDMH) with the two methyl groups attached to different, adjacent nitrogen atoms, is not used as a rocket propellant and is only an unwanted contaminant and decomposition product that must be dealt with carefully due to its toxicity. The following sections discuss dimethylhydrazines in the order of importance, UDMH first and SDMH last.

## 1 Unsymmetrical Dimethylhydrazine

Unsymmetrical dimethylhydrazine and asymmetrical dimethylhydrazine, 1,1-dimethylhydrazine, *N,N*-dimethylhydrazine, 2-methyl-2,3-diazapropane, UDMH, also referred to as “Dimazine,”  $(\text{CH}_3)_2\text{NNH}_2$ ,  $\text{C}_2\text{H}_8\text{N}_2$ , CAS RN [57-14-7], also [88733-28-2], is the most commonly produced hypergolic fuel (see [1, 2]).

### 1.1 Production of Unsymmetrical Dimethylhydrazine

Unsymmetrical dimethylhydrazine did not have any industrial applications before it was identified and developed as a rocket propellant. UDMH is a textbook example of how the use of a chemical expanded from a rarely used chemical (used only in test tube quantities) to a major industrial product. It would be interesting to trace back the history of UDMH from when it was first made to the point of large-scale production when it became an important ingredient [3]. The history of all hydrazines deserves to be explored in a book similar to the very entertaining, anecdotal book on the history of boranes written in 1991.

Next to hydrazine (and hydrazine hydrate), 1,1-dimethylhydrazine is probably the hydrazine derivative with the largest cumulative production quantity on record. This is due to its use as a bipropellant fuel in liquid-fueled rockets in many countries around the world. To satisfy the temporarily high demand for this chemical, several alternate production methods have been developed as an intermediate solution [4], including industrial-scale production methods and one involving *N*-nitrosodimethylamine,  $(\text{H}_3\text{C})_2\text{NNO}$ , NDMA, which is a proven animal carcinogen. However, concern about the toxicity of nitrosamine intermediates has caused a major shift in the industrial practice of UDMH production over the past 50 years. At one point, it even led to aerospace managers initiating an intensive search during the 1970s to look for alternate methods that avoid the use of carcinogenic intermediates [5].

A temporary UDMH shortage in the United States (US) in 1973 prompted the formation of a Joint UDMH Task Group which studied a variety of alternative processes that do not require the use of NDMA. This included chloramination [6], hydrazine methylation, urea processes, nitramine processes [7, 8], and others [9]. A cost comparison of different processes to produce monomethylhydrazine (MMH) and UDMH was conducted in 1978. This concluded that (based on a 6.5-year amortization schedule) the estimated product cost for UDMH using the chloramine-Sisler process would have been \$4.53/lb. MMH was estimated to cost \$6.12/lb rather than \$6.73/lb as reported from the Raschig process used in 1978 (1978 US dollars) [10]. A preferred process would have been one that can produce both UDMH and MMH using the same equipment. Methylation of hydrazine might have resulted in a price of \$8/lb for UDMH and \$12/lb for MMH (1978 US dollars). The nitramine process was expected to be even more expensive, namely, \$15/lb UDMH. As the search for alternate UDMH production methods continued, the US supply of Aerozine-50 dropped to 380000 lb at one point, which was equivalent to only six Titan-II launches [11].

### 1.1.1 Preparation of UDMH Using a Modified Raschig Process

A variation of the Raschig process involves a chloramine solution (which is prepared using the same method as when hydrazine itself is the desired product) that is reacted with dimethylamine (DMA) instead of ammonia. In one example [12, 13], a 17-kg/h stream of 10%  $\text{NH}_3$  solution with 0.06% glue was reacted at 273 K (0 °C) with 25 kg/h of NaOCl solution containing 115 g of active chlorine per liter. DMA was added to the primary reactor effluent at a rate of 10 kg/h. The temperature was then raised to ambient to allow the reaction to go to completion. The UDMH can be extracted from the reaction mixture with an inert solvent that does not mix with water. Solvents proposed for this purpose are aniline, *o*-toluidine, *m*-toluidine, *N,N*-dimethylaniline, and xyli-dine.

When producing UDMH, MMH, or hydrazine, it is important during all modifications of the Raschig process that an efficient way of making chloramine without losing too much active chlorine is employed. The chloramine yield depends on the pH of

the ammonia or ammonium chloride solution reacting with sodium hypochlorite and needs to be optimized [14].

The production of UDMH using the modified Raschig process may form small amounts of hydrazine as a by-product. While the presence of a little hydrazine does not interfere when UDMH is used as a rocket fuel, it may lead to undesirable side reactions when UDMH is intended to be used for the synthesis of pharmaceutical or agrochemical products. Traces of hydrazine can be selectively removed from UDMH solutions by heating it in contact with catalysts that do not destroy any alkylhydrazines, for instance nickel supported on silica/alumina, nickel-nickel oxide mixture supported on silica/alumina, or rhodium supported by carbon at a temperature of between 333 and 393 K (60 and 120 °C) [15].

The kinetics of the reaction

were studied at different reactant ratios, pH (between 12 and 6 mol/L of alkali hydroxide), and temperature (298–333 K = 25–60 °C) [16]. The reaction is first order in both reactants, and the reaction is independent of the concentration of alkali hydroxide up to about pH = 12.5. At higher alkalinities, catalysis by hydroxide ions was observed and the rate constant was a linear function of hydroxide ions activity. The yield of the reaction increased from pH = 12 to 13.5 on account of the decrease of the rate of dimethylhydrazine oxidation by monochloramine, and the reaction went beyond 14 on account of the diminution of monochloramine decomposition.

Another kinetic model of UDMH formation using the Raschig process covered an application range from pH 8 to 14.64 (4 mol/L NaOH) [17]. It assumed that the synthesis is controlled by the acid-base dissociation equilibria:

and by the following concurrent elementary reactions: **(1)** dimethylhydrazine formation molecular ( $\text{NH}_2\text{Cl}/(\text{CH}_3)_2\text{NH}$ ) and ionic ( $\text{NHCl}^-/(\text{CH}_3)_2\text{NH}$ ) processes; **(2)** dimethylchloramine formation from  $\text{NH}_2\text{Cl}$  and  $(\text{CH}_3)_2\text{NH}_2^+$ ; **(3)** UDMH catalytic oxidation by  $\text{NH}_2\text{Cl}$  and dimethyldiazene  $(\text{CH}_3)_2\text{N}^+=\text{N}^-$  intermediate formation; **(4)** diazene decomposition to yield formaldehyde dimethylhydrazone (FDMH); **(5)** degradation of  $(\text{CH}_3)_2\text{N}^+=\text{N}^-$  by  $\text{NH}_2\text{Cl}$ ; **(6)** alkaline hydrolysis of chloramine. The synthesis can be expressed by a differential system of which the integration allows the prediction of the evolution of mixtures in terms of concentration, pH, and temperature. It also allows a numeric evaluation of FDMH, which is a troublesome by-product of the UDMH manufacture. Significant examples were selected in different pH ranges and concentrations to test the agreement between experimental and

calculated curves. It was found that the reaction is first order in each of the first two reactants and is independent of alkali concentration in the range of pH 12.5. Beyond this point, a catalytic action of alkali was observed and the rate became dependent on pH. The UDMH yield went through a maximum at pH = 14. One of the yield-limiting reactions is a reaction of UDMH with chloramine that leads to tetramethyltetrazene and ammonium chloride.

In a laboratory study, a 0.9-kg/h (2-lb/h) bench-scale reactor for chloramine production was operated to determine optimum operating conditions [10]. An empirical equation was derived that calculates the chloramine yield (as a fractional decimal) as a function of reactant ratios and temperatures:

$$\text{Yield} = A(1 - e^{-B\lambda})$$

$$A = a + bt + ct^2$$

$$B = d + f \frac{[\text{N}_2]}{[\text{Cl}_2]}$$

$$\lambda = \frac{[\text{NH}_3]}{[\text{Cl}_2]}$$

with  $a = -2.447695$ ,  $b = 0.013631$ ,  $c = -8.331248$ ,  $d = 0.146832$ ,  $e = 2.7182818$ ,  $f = 0.023463$ , and  $t = \text{temperature, } ^\circ\text{F}$ . Other topics investigated were the analysis of  $\text{ClNH}_2$  in effluent from the first-stage reactor, kinetics of  $\text{ClNH}_2$  reaction with amines (MMH or UDMH), the efficiency of the reactor stirrer, phase diagrams of  $\text{CH}_3\text{NH}_2$ - $\text{NaOH-H}_2\text{O}$  and  $(\text{CH}_3)_2\text{NH-NaOH-H}_2\text{O}$ , product purification by extraction, and by-product analysis. Recommended molar ratios of  $\text{NH}_3:\text{Cl}_2$  for first-stage reaction were 10:1. In the contactor second-stage reactor, the preferred amine: $\text{NaOH}:\text{ClNH}_2$  ratios were 4.5:1.6:1.4 for UDMH and 9.0:1.2:1.0 for MMH. Based on data obtained with the 0.9-kg/h reactor, scale-up to an 18-kg/h pilot plant and 182-kg/h production plant was considered feasible as the next step.

Synthesizing different hydrazines by an indirect Raschig process by introducing a substituted chloramine ( $\text{R}_1\text{R}_2\text{NCl}$ ) into liquid ammonia under pressure to obtain the corresponding hydrazine ( $\text{R}_1\text{R}_2\text{NNH}_2$ ) led chemists to propose a new mechanism involving a chlorine transfer reaction. This was in disagreement with mechanisms reported in the literature [18]. Thus, the reaction of chloramine and the amine ( $\text{R}_1\text{R}_2\text{NH}$ ) occurs first. Chloramine reacts immediately with the substituted amine, in agreement with the direct Raschig process, to produce the hydrazine. Under these conditions, the nature of the hydrazine is kinetically controlled by the excess amine. As such, it becomes possible to synthesize different hydrazines from the same substituted chloramine. This mechanism was validated by synthesizing UDMH, *N*-aminopiperidine, and *N*-amino-3-azabicyclo[3.3.0]octane.

After an exhaustive study of the system ammonia/dimethylchloramine in liquid ammonia, it was interesting to compare the reactivity of this system in liquid ammo-

nia with the same system in an aqueous medium [19]. Dimethylchloramine prepared in a pure state underwent dehydrohalogenation in an alkaline medium. The principal products formed were *N*-methylmethanimine, 1,3,5-trimethylhexahydrotriazine, formaldehyde, and methylamine. The kinetics of this reaction was studied using ultraviolet (UV), gas chromatography (GC), and high-performance liquid chromatography (HPLC) as a function of temperature, initial concentrations of sodium hydroxide, and chlorinated derivative. The reaction was of the second-order and obeyed an E2 mechanism

$$k_1 = 4.2 \times 10^{-5} \text{ mol}^{-1} \text{ s}^{-1}, \quad \Delta H = 82 \frac{\text{kJ}}{\text{mol}}, \quad \Delta S = -59 \text{ J mol}^{-1} \text{ K}^{-1}.$$

The oxidation of unsymmetrical dimethylhydrazine by dimethylchloramine involves two consecutive processes. The first step follows the first-order law for haloamine and hydrazine, leading to the formation of an aminonitrene intermediate

$$k_2 = 150 \times 10^{-5} \text{ mol}^{-1} \text{ s}^{-1}.$$

The second step corresponds to the conversion of aminonitrene into FDMH at pH 13. This reaction followed the first-order law

$$k_3 = 23.5 \times 10^{-5} \text{ s}^{-1}.$$

The dimethylchloramine-ammonia interaction corresponds to an SN2 bimolecular mechanism

$$k_4 = 0.9 \times 10^{-5} \text{ mol}^{-1} \text{ s}^{-1}, \quad \text{pH} = 13, \quad \text{and} \quad T = 298 \text{ K} = 25^\circ \text{C}.$$

The kinetic model formulated based on the above reactions showed that the formation of UDMH in an aqueous medium is limited by strong competition from the dehydrohalogenation of dimethylchloramine and the oxidation of UDMH formed by the original chlorinated derivative.

The formation of FDMH by oxidation of UDMH by chloramine during the UDMH synthesis is a very undesirable side reaction. Therefore, conditions favoring this reaction must be avoided. The kinetics of UDMH oxidation by chloramine have been investigated in an aqueous solution in terms of concentration, pH (8–13.5), and temperature (288–308 K = 15–35 °C) [20]. The overall reaction, first-order in both reactants, is the result of two competitive steps. Catalysis by hydrogen ions was observed and the apparent rate constant involved two terms, one being pH-independent the other one varying linearly with the acidity function. The entropy and enthalpy of activation of the molecular process have been established at 298 K (25 °C). In alkaline media (pH ≥ 13), the major product of the reaction identified by mass spectrometry (MS) was FDMH (CH<sub>3</sub>)<sub>2</sub>NN=CH<sub>2</sub>. In neutral or weakly basic solution (pH ≤ 8), the only organic product formed was tetramethyl-2-tetrazene (CH<sub>3</sub>)<sub>2</sub>NN=NN(CH<sub>3</sub>)<sub>2</sub>. A mixture of these two compounds was obtained for intermediate pH values.

The effect of acidification on the chloramine-dimethylamine reactivity was further investigated as a function of pH (13–8) and temperature (292–305 K = 19–32 °C) [21]. Kinetics results showed the existence of two competitive reactions involving chloramine with neutral and ionic forms of the amine. According to a second-order process, they lead to the formation of dimethylhydrazine ( $k_1 = 68 \times 10^{-3} \text{ L mol}^{-1} \text{ s}^{-1}$ ;  $T = 298 \text{ K}$ ) and dimethylchloramine ( $k_2 = 210 \times 10^{-3} \text{ L mol}^{-1} \text{ s}^{-1}$ ;  $T = 298 \text{ K} = 25^\circ \text{C}$ ). The rate bimolecular constant calculated from the total concentration of reactants may be expressed by an equation of the form

$$k_{\text{obs}} = k_1 \alpha_A + k_2 \beta_A$$

where  $\alpha_A$  and  $\beta_A$  are coefficients that depend on pH and the protonation constants of dimethylamine. The enthalpy and entropy of activation for the ionic process have been determined at 298 K (25 °C). Another potential mechanism involving  $\text{NH}_3\text{Cl}^+$  and  $(\text{CH}_3)_2\text{NH}$  have been examined and a correlation between the two models was established.

While modeling the kinetics of the preparation of UDMH under industrial conditions, an analysis of the kinetic data enabled the operators to define the optimal range for synthesis (pH = 13–14.64) [22, 23]. For this interval, a theoretical model was established and physical correlations between the initial and final states were developed. This model was based on the following reactions: **(1)** dimethylhydrazine formation via molecular and ionic processes; **(2)** UDMH oxidation by  $\text{NH}_2\text{Cl}$  and FDMH formation; **(3)** alkaline hydrolysis of chloramine. The influence of the absolute concentration of starting materials showed that the yields  $p_1 = [\text{UDMH}]_\infty / [\text{NH}_2\text{Cl}]_0$  and  $P_2 = [\text{UDMH}]_\infty / [(\text{CH}_3)_2\text{NH}]_0 - [(\text{CH}_3)_2\text{NH}]_\infty$ , approach the limiting values  $p_1$  and  $p_2$ , which depend solely upon the initial molar ratio  $p = [(\text{CH}_3)_2\text{NH}]_0 / [\text{NH}_2\text{Cl}]_0$ , the pH, and the temperature. The concentrations of the by-product FDMH as a function of the degree of conversion of the reactants have been calculated and operating conditions for the synthesis that avoids the troublesome FDMH formation have been proposed.

Conditions leading to the formation of FDMH by UDMH oxidation by chloramine must be avoided [24]. The kinetics of UDMH oxidation by chloramine has been investigated in aqueous solutions as a function of concentration, pH (8–13.5), and temperature (288–308 K = 15–35 °C). The overall reaction, first-order in both reagents, is the result of two competitive steps. Catalysis by hydrogen ions was observed and the apparent rate constant involved two terms, one being pH-independent the other one varying linearly with acidity function  $h_0$ . The entropy and enthalpy of activation of the molecular process have been established at 298 K (25 °C). In alkaline media (pH  $\geq$  13), the major product of the reaction identified using MS was the FDMH  $(\text{CH}_3)_2\text{NN}=\text{CH}_2$ . In neutral or weakly basic solution (pH  $\leq$  8), the only organic product formed is tetramethyl-2 tetrazene  $(\text{CH}_3)_2\text{NN}=\text{NN}(\text{CH}_3)_2$ . A mixture of these two compounds was obtained for intermediate pH values.

### 1.1.2 Methods of UDMH Product Separation

Because the UDMH content in Raschig primary product effluents is only 3% or less, a multi-step distillation in a very efficient distillation column is required to separate unreacted reactants, products, and by-products. The distillation is facilitated by adding 1–30% NaOH [25, 26]. For instance, 100 parts of synthesis liquor containing 3% UDMH, 8% H<sub>2</sub>O, and 10% NaCl (balance amine and ammonia) were mixed with 12.8 parts of solid NaOH. The distillation in a column with 11 theoretical trays, operating at a 75:1 reflux ratio, resulted in a 90% recovery of 95% UDMH. A typical reaction raw product prior to distillation was described as consisting of 1.27 mol/kg ammonia, 4.38 mol/kg dimethylamine, 0.026 mol/kg FDMH, 0.56 mol/kg UDMH, 33.0 mol/kg water, 2 mol/kg NaCl, and 0.45 mol/kg NaOH [27]. It was separated in a distillation apparatus consisting of two columns, one with two plates to remove volatiles and small amounts of water and a second with seven plates to separate water and UDMH from the other volatiles. This method is said to avoid the precipitation of salts that may clog the pipes.

There have been attempts to extract UDMH from the reaction mixture by crystallization or by distillation from a concentrated solution. To do that, the solid-liquid and liquid-liquid equilibria in the ternary-systems (*N,N*-dimethylhydrazine sodium-hydroxide water and *N,N*-dimethylhydrazine sodium-chloride water) had to be measured [28]. In another example, the UDMH was recovered by adding 50% NaOH, filtering off the NaCl, and extracting with aniline [12]. The extract, which contained 3.5% UDMH, was dried over solid NaOH and separated via distillation. At 298 K, a single solid phase (NaCl) was observed in the UDMH-NaCl-H<sub>2</sub>O system. In the ternary system UDMH-NaOH-H<sub>2</sub>O, a very wide miscibility gap was observed. The invariant point compositions were (in percent by weight) 94.5% UDMH + 5.5% H<sub>2</sub>O (no NaOH) and 48.1% NaOH + 1.4% UDMH + 51.5% H<sub>2</sub>O [29–31].

### 1.1.3 Single-Step SNPE Process

A particularly elegant route to UDMH is the continuous SNPE process developed in France that starts with aqua ammonia, dimethylamine, and sodium hypochlorite [32]. The undesirable formation of the *N,N*-dimethylhydrazone of formaldehyde (CH<sub>3</sub>)<sub>2</sub>N=N=CH<sub>2</sub> (also called methylene dimethyl hydrazine) as a by-product can be suppressed by adding 0.5–2 vol.-% hydrazine in the form of hydrazine hydrate to the reaction mix [33]. The use of hydrazine reduces the by-product concentration from 6.4 to 2.4% in the raw product. A raw product containing 16% UDMH, 8% NH<sub>3</sub>, 8% (CH<sub>3</sub>)<sub>2</sub>NH, 2.3% H<sub>2</sub>C=N–N(CH<sub>3</sub>)<sub>2</sub>, and 71% H<sub>2</sub>O can be separated by distillation using 2-propanol as an auxiliary fluid [34]. The hydrazone goes over with the 2-propanol and can then be hydrolyzed to obtain more UDMH. Under slightly different conditions, but still using 2-propanol, UDMH can be obtained directly from raw reaction products after adding sufficient sodium hydroxide to form two separate layers (32% NaOH) and distilling on a column at 361–363 K (190–195 °F) [35]. In a batch process, the end of

distillation of pure UDMH was indicated when the pot temperature rapidly increased to 372 K (210 °F).

#### 1.1.4 Preparation of UDMH Using the Sisler Process

Using the Sisler process, UDMH can be prepared either from chloramine and DMA [36–38] or from chlorodimethylamine and ammonia [39]. Both can be prepared in either the gas phase or in a non-aqueous solvent system. Improved yields can be obtained by operating in a two-phase system [40]. *N*-Chlorodialkylamines are not sufficiently reactive with ammonia at ambient temperature to give good dialkyl-hydrazine yields. Thus it takes alkali or temperatures above the normal boiling point of ammonia or both to achieve acceptable conversion. Reacting dimethylchloramine with ammonia in a pressure bomb at 0.9 MPa and 293 K for 45 minutes in the presence of solid KOH produced only a modest UDMH yield of 26% of the theory [39].

To find a suitable replacement for the nitrosamine process, the Sisler process was one of several investigated at the Martin Marietta Corp. as an alternative approach [7, 8].

The chloramination of DMA in a solution of KOH in 1-butanol was carried out in the presence of NH<sub>3</sub> at room temperature [41]. The major products were 1,1-dimethylhydrazine, the dimethylhydrazone of formaldehyde, and 1,1,4,4-tetramethyl-2-tetrazene. Subsequently, 1,1-dimethylhydrazine was reacted with ammonia-free chloramine in ether solution. The products included CH<sub>4</sub>, N<sub>2</sub>, the dimethylhydrazone of formaldehyde, and 1,1,4,4-tetramethyl-2-tetrazene. This is a UDMH yield-limiting reaction that must be suppressed. The reactions of 1,1-dimethylhydrazine with HgO and with Ag<sub>2</sub>O also resulted in 1,1,4,4-tetramethyl-2-tetrazene.

Attempts to manufacture UDMH by the anhydrous Sisler process from DMA and chloramine were not always very successful [42]. Although yields as high as 71% UDMH were achieved in pure DMA at low chloramine concentrations, there was a marked decrease in product yield when higher ClNH<sub>2</sub> concentrations were employed [43]. The problem is caused by undesirable side reactions, leading to tetramethyltetrazene

or FDMH

Hydrazone is a particularly troublesome by-product because it cannot be removed by conventional distillation procedures. While tetramethyltetrazene may accumulate in UDMH distillation columns and cause explosions. As such, tetramethyltetrazene accumulations must be avoided by periodically purging the column.

A process for the preparation of UDMH in an anhydrous reaction medium was developed on a laboratory scale [6]. The method consisted of generating chloramine in the gas phase by reacting an excess of ammonia with chlorine diluted with nitrogen. After removal of the ammonium chloride by-product, the gaseous reaction product was absorbed in a suitable hydrocarbon solvent such as xylene. The yield of chloramine (based on chlorine input) was 90%. The chloramine solution was then reacted with excess liquid DMA or a solution of DMA in xylene at temperatures of 273 to 278 K (0 to 5 °C) with efficient stirring. The yields of UDMH obtained were 50 to 60%. Isolation of UDMH was achieved by distillation. It was found that MMH can be prepared using this method as well. UDMH can also be prepared by a variation of the above process in which the chloramine from the gas-phase generator is introduced directly into a liquid two-phase system consisting of aqueous sodium hydroxide and dimethylamine. UDMH was produced in high yields (80%) in relatively high concentrations. The activation energy of UDMH formation was found to be 41 kJ/mol (9.8 kcal/mol), in agreement with that reported by other authors (40.2 kJ/mol = 9.6 kcal/mol) [7]. The activation energy of the troublesome side reaction leading to FDMH was 14.5 kcal/mol. Therefore, the undesired side reaction becomes more important at higher temperatures. The rate of this side reaction is 600 times faster than the one leading to the product UDMH (in anhydrous organic solvents at 273 K) [43]. It is obvious that under these conditions, one is fighting an uphill battle. The UDMH concentration achieves only a low stationary concentration early in the reaction, and any further additions of  $\text{ClNH}_2$  do not improve the UDMH yield. The relative ratios of formation of FDMH to UDMH are more favorable to UDMH production in water or ammonia as a process solvent than in anhydrous organic solvents. The extraction of the product hydrazines from the slush reaction mix of the Sisler-Kelmers process is facilitated by the addition of 2–5 parts of hydrocarbon, such as *n*-heptane, filtering the undissolved hydrochlorides, and distilling the filtrate [44, 45].

A stopped-flow technique was used to study the kinetics of the  $\text{ClNH}_2 + (\text{CH}_3)_2\text{NH}$  reaction in chloroform, dioxane, and diethyl ether [43].

A report by the University of Florida included six appendices that examined the chloramination of dimethylamine, synthesis of MMH in non-aqueous solvents, and also the oxidation of UDMH and MMH by oxygen, which are unwanted side reactions. The chloramination of DMA in a solution of KOH in *n*-butanol in the presence of  $\text{NH}_3$  at room temperature produced UDMH but also formed large amounts of by-products in the form of tetramethyltetrazene (TMTZ) and the dimethylhydrazone of formaldehyde [46]. The UDMH yield was only 30% of the theoretical yield based on the amount of chloramine consumed. To study the yield-limiting follow-on reactions, UDMH was reacted with chloramine in ether at 293 K (20 °C). Reaction products included methane, nitrogen,  $(\text{CH}_3)_2\text{NN}=\text{CH}_2$ ,  $(\text{CH}_3)_2\text{N}-\text{N}=\text{N}-\text{N}(\text{CH}_3)_2$ , and some unreacted UDMH. Relatively pure tetramethyltetrazene could be obtained by oxidizing UDMH with mercuric oxide in ether solution. The TMTZ yield was 97% after 1 h. However, with continued stirring, the TMTZ decomposed to FDMH (also called methylene

dimethyl hydrazine) within 23 h. In earlier reports [47], the formation of TMTZ during the reaction of UDMH with chloramine was postulated to occur by way of the dimethyldiazene radical  $(\text{CH}_3)_2\text{N}^+=\text{N}^-$ , the dimerization of which would lead to TMTZ. The exact mechanism is still uncertain. A similar mechanism involving dimethyldiazene and diazomethane had been proposed [48]:

The dimethyldiazene could also be prepared by oxidation of UDMH with silver oxide. By reacting the dimethyldiazene thus formed with diazomethane derivatives, it could be shown that this mechanism is not the one that leads to FDMH. Another undesirable follow-on product during the reaction of UDMH with chloramine is 2,2-dimethyltriazanium chloride [48]:

If samples of this salt are needed for comparison purposes, it can be prepared in good yield by reaction of UDMH with chloramine in ethereal solution. It is stable at room temperature and reacts with neither ammonia nor UDMH. It can be recrystallized from UDMH in which it is moderately soluble.

Theoretically, UDMH can be made from dimethylchloramine and ammonia. However, the reaction of the excess dimethylchloramine with the UDMH thus formed leads to unwanted by-products that limit the UDMH yield [49]. Quite often in various UDMH production processes, FDMH is obtained as an undesirable by-product. Controlled hydrolysis of these unwanted hydrazones can yield some additional UDMH.

### 1.1.5 Preparation of UDMH from Urea

A temporary UDMH shortage in the US in 1973 prompted a variety of studies on alternative processes for the production of UDMH, which included chloramination [6], hydrazine direct methylation, urea processes [50], and nitramine processes [7]. These studies were sponsored by the Space and Missile Systems Organization (SAMSO), the Air Force Logistics Center (AFLC) in San Antonio, and the Air Force Rocket Propulsion Laboratory (AFRPL), based in Edwards AFB, CA [9]. After completion of the urea process study [50], SAMSO awarded a contract to the Illinois Institute of Technology Research Institute (IITRI) to investigate product purification and waste product disposal of the crude amine mixtures resulting from the chloramine process. In evaluating the chloramine versus the urea process, it was concluded that both are feasible, however, the capital costs for the urea process were considerably greater [10]. A cost comparison of different processes to produce MMH and UDMH was conducted in 1978. This was based on a six-and-a-half-year amortization schedule. The exercise concluded

that the estimated product cost using the chloramine-Sisler process would be \$4.53/lb for UDMH and \$6.12/lb for MMH compared to \$6.73/lb MMH using the Raschig process used in 1978 (1978 US dollars). Another process, the methylation of hydrazine, was said to result in \$8/lb for UDMH and \$12/lb for MMH. The nitramine process was expected to be even more expensive, namely, \$15/lb UDMH. Of course, these cost comparisons mean nothing in view of the process equipment improvements that may have been made in the interim.

To avoid the use of carcinogenic NDMA as an intermediate in the production of UDMH, numerous other synthesis routes have been evaluated. One such route was the modification of the urea process for hydrazine, starting with *N,N*-dimethylurea instead of urea [51, 52]. Another possibility to produce UDMH is by the urea process based on phosgene [53]:

Initially, they attempted to run the process without removing the  $\text{NH}_4\text{Cl}$  from the dimethylurea. Removal of  $\text{NH}_4\text{Cl}$  by reaction with 50% aqueous NaOH was possible in laboratory tests but less effective in a production plant. Optimization of process conditions and the identification of reaction intermediates during the reaction of dimethylurea with hypochlorite were hampered by a lack of analytical methods. *N,N'*-Dimethyl-*N*-chlorourea and *N,N*-dimethylamino isocyanate are likely intermediates in the reaction leading to UDMH. Hypochlorite not only initiated the desired Hoffmann rearrangement of the amide but also reacted with the methyl groups, which was very undesirable. Dichloro- and trichloromethane were found in the by-products.

UDMH can be made by base-assisted chlorination of urea by dimethylchloramine [54]. Dimethylchloramine prefers to abstract the H-atom from urea. However, the chlorination of urea occurs, and tetramethylhydrazine forms as a result of the coupling of the dimethylamino radicals. Fairly good yields of UDMH are obtainable in methanol.

### 1.1.6 Preparation of UDMH by Direct and Indirect Methylation of Hydrazine

Direct methylation of hydrazine or hydrazine hydrate with dimethyl sulfate in an ice bath with vigorous agitation resulted in a mixture of 32% MMH and 67.6% UDMH with a trace (0.3%) of trimethylhydrazine [55]. Whereas this mixture may be undesirable for a purely organic chemist, the mix is perfectly suitable as a rocket fuel without further separation. A laboratory method was developed for the preparation of MMH and UDMH in good yields by the direct methylation of hydrazine with dimethyl sulfate [56]. The relative quantities of MMH and UDMH obtained can be varied by altering the mol ratios of dimethyl sulfate to hydrazine (hydrate). Small amounts of symmetrical

dimethylhydrazine and trimethylhydrazine can also be formed as by-products in this reaction. The methylation procedure was employed to manufacture several hundred pounds of MMH and UDMH for distribution to various agencies for their test programs in the 1950s.

Methylation of hydrazine hydrate results in an azeotrope of UDMH and methanol that is difficult to separate. If dimethyl sulfate is added to UDMH, the reaction product consists of 1,2-dimethylhydrazine (SDMH) and trimethylhydrazine.

### 1.1.7 Reductive Methylation of Acethydrazide

Reductive methylation of acethydrazide (acetyl hydrazine, prepared by condensing hydrazine with ethyl acetate) forms an alkylated product that can be hydrolyzed to yield 84% UDMH [57–59].

Reductive alkylation of acetyl hydrazine, which is then hydrolyzed and converted to UDMH, is an attractive process for getting high yields of UDMH in a safe production process. The effects of pressure, temperature, and the amount of Pd/C catalyst on the yield of the reductive alkylation of acetyl hydrazine were studied to optimize the yield of this process [60]. The reductive methylation with formaldehyde and hydrogen is achieved via Pd-C catalysts. Catalyst poisoning due to unreacted hydrazine is avoided by bubbling carbon dioxide through the mixture. This process was temporarily used by Uniroyal Inc. to produce UDMH after other UDMH producers had withdrawn from the market. Uniroyal later discontinued this operation and returned to purchasing UDMH from other sources.

### 1.1.8 Isotope-Labeled UDMH

Isotope-labeled UDMH is needed for toxicokinetic studies of UDMH metabolism in animals, for spectroscopic studies of the molecular structure by identifying molecular vibrations, and for kinetic studies in the formation and decomposition of UDMH. Substitution of hydrogen on nitrogen by deuterium is relatively easy and the rate of substitution can be measured by proton exchange rate measurements.

*N,N*-[Methyl-<sup>14</sup>C]-Dimethylhydrazine hydrochloride was synthesized in two steps: dimethylation of acetophenone hydrazone with <sup>14</sup>C-methyl iodide in the presence of potassium in liquid ammonia, followed by acid-catalyzed hydrolysis of the hydrazone. This afforded this chemical a yield of 60% (>97% radiochemical purity) [61].

### 1.1.9 Preparation of UDMH via NDMA

Several of the processes for the production of UDMH described on the following pages are dependent on NDMA as an intermediate. Because NDMA and other nitrosamines are human carcinogens, these processes must be used with extreme precaution to avoid worker exposure and environmental pollution. One UDMH-production plant operated by FMC in Baltimore, MD, had to be shut down in 1975 because NDMA in levels of 0.3 to 12 ppb was found in the air surrounding the plant.

Methods for NDMA production have become very unpopular due to occupational hygiene and environmental pollution concerns. Nonetheless, the methods are listed here for reference purposes. If nothing else, this is the type of reaction one should avoid. An NDMA 98.8% yield can be obtained by a continuous process by reacting DMA with a mixture of nitric oxide (NO) and air, maintaining an excess of NO, and maintaining acidic conditions with the addition of hydrochloric acid [62, 63]. In another process, NDMA was obtained in 94% yield by reacting a mixture of dimethylammonium sulfate and sodium nitrite (initial pH 9.5) slowly with sulfuric acid [64]. After the pH had dropped to four and the reaction had ceased, a slight excess of sodium nitrite was added as a 40% solution before distillation. This procedure has been used for large-scale NDMA production at the rate of 450 kg/h.

NDMA can be separated from the reaction mix by distillation and phase separation with caustic [65]. One-pot synthesis of UDMH avoids the isolation of NDMA. This is prepared using DMA and dinitrogen tetroxide with potassium carbonate. A palladium catalyst is added, which reduces the raw product with high-pressure hydrogen immediately after the nitrosation is complete [66].

The more detailed chapter on reduction methods for NDMA that was published in an earlier book [67] has been abbreviated and is not repeated here. Reduction methods include the reduction of NDMA with metals in acidic or alkaline solution, electrolytic reduction, catalytic reduction with hydrogen gas, and NDMA reduction with metal hydrides or sodium dissolved in liquid ammonia.

### 1.1.10 UDMH Preparation from Sodium Amide and Dimethylchloramine

Admittedly it is more expensive to react chloramines with alkaline metal amides instead of free ammonia. However, the yields can be better because the alkaline metal chloride precipitates in the presence of tertiary amine solvents. The only advantage of this method is that it avoids the use of water and it results directly in anhydrous hydrazines. Thus, UDMH is obtained in 60% yield by reacting *N*-chlorodimethylamine in tripropylamine with sodium amide in liquid ammonia at 238 K [68–72].

### 1.1.11 Separation of Water and UDMH

As explained earlier, mixtures of UDMH and water are not easy to separate by simple distillation because UDMH forms an azeotrope with water. The problem with separating the desired alkylhydrazine from the reaction mixture is similar to the problem encountered earlier with MMH and water. Usually, the azeotrope is broken by adding sodium hydroxide to the mixture, following which the pure MMH or UDMH can be distilled off [25]. Monoethanolamine can be used as an auxiliary fluid to separate UDMH and water by distillation [73].

The methods used for separating UDMH and water depend on the amount of water in the UDMH or the amount of UDMH in the water [74]. Process liquors from the Raschig process usually contain only 3% UDMH.

#### 1.1.11.1 Concentrating Dilute Solutions of UDMH in Water

Pervaporation of process liquid containing only less than five percent of UDMH in water is a more economical process than distillation. In pervaporation, the feed mixture is contacted with a non-porous perm-selective membrane. Separation is, in general, explained by the steps of sorption into, diffusion through, and desorption from the membrane. The latter is usually considered to be fast and expected to take place at equilibrium, while diffusion is kinetically controlled and the slowest step of the process. Permeation is dependent on sorption and diffusion steps. The driving force for the separation is created by maintaining a pressure lower than the saturation pressure on the permeate side of the membrane. The mechanism of separation is usually explained in terms of sorption-diffusion processes.

Dehydration of hydrazine or MMH using ethyl cellulose membranes has been demonstrated and similar techniques can be used for UDMH, except that ethyl cellulose is not compatible with UDMH [75, 76]. However, ethyl cellulose membranes cannot be used to dehydrate UDMH because ethyl cellulose is degraded rapidly in UDMH.

Chitosan, a derivative of the naturally abundant biopolymer chitin, is fully stable in anhydrous UDMH and hence can be selected for its dehydration ability, keeping in mind its highly hydrophilic nature and good mechanical strength. The promising potential of chitosan as a pervaporation membrane has already been exploited for the dehydration of alcohols such as ethanol and isopropanol [77].

Cross-linked chitosan membranes synthesized using glutaraldehyde and characterized by IR and XRD spectroscopic methods were applied to the pervaporation-based dehydration of UDMH [78]. The characterization techniques were an efficient tool in identifying polymer-liquid interaction sites and the separation mechanisms involved. The cross-linked polymer was found to have good potential for the separation of the aqueous azeotrope (20 mass-% UDMH) and its enrichment to >90% purity. An equilibrium sorption study examined the preferential affinity of the membrane toward the two penetrating liquids. The pervaporation performance of the membrane was eval-

uated by varying the experimental parameters of feed composition, membrane thickness, and permeate pressure. Similar membranes can be used for the pervaporation of MMH from aqueous solutions.

NaA zeolite membranes have been formed on porous mullite tubes and tested for the pervaporation of dilute UDMH solutions in water [79]. The seeded supports were prepared by dipping the mullite supports in an 8% NaA zeolite suspension in a single step. After dipping, the supports were dried at 373 K (100 °C) for 3 h. Other tubes received five coatings. Most initial tests were conducted with ethanol/water mixtures as a surrogate liquid and only a few tests were conducted with 2% UDMH solutions at a temperature of 303 K (30 °C) and a pressure of 1.5 mbar at the permeate side, with test durations of 30–60 minutes. For low concentrations of UDMH, the zeolite NaA membrane was better than the zeolite hydroxy sodalite membrane. However, for high concentrations of UDMH, a zeolite hydroxy sodalite membrane was recommended.

Hydroxysodalite zeolite was coated on an external surface of porous mullite supports using hydrothermal synthesis and water/UDMH mixtures were separated at ambient temperature and atmospheric pressure by pervaporation using the hydroxysodalite zeolite membranes [80–83]. The membranes demonstrated very high selectivity of water for all water/UDMH mixtures. A separation factor as high as 52000 was obtained for a UDMH feed concentration of 5%. Total mass flux was up to  $3.95 \text{ kg m}^{-2} \text{ h}^{-1}$ . The results confirmed the good performance of hydroxysodalite zeolite membranes for the dehydration of water/UDMH mixtures.

Mordenite is another zeolite mineral that was evaluated in pervaporation experiments. Mordenite membranes were prepared on the outer surface of mullite ceramic tubes via hydrothermal synthesis and evaluated for dehydration pervaporation of water/UDMH mixtures [84]. Highly water-selective mordenite membranes were prepared and the optimum reaction condition was found to be 24 h crystallization time and 443 K (170 °C) crystallization temperature. The effect of gel composition on the separation factor and water flux of the water-UDMH mixtures was investigated. XRD patterns showed that mordenite was the only zeolite material that was present in the membrane. The morphology of the supports subjected to crystallization was characterized by scanning electron microscope (SEM). In pervaporation of the water or in UDMH mixtures with higher UDMH contents, the membrane exhibited a hydrophilic behavior. The best membranes had a water flux of  $2.67 \text{ kg m}^{-2} \text{ h}^{-1}$  at 303 K (30 °C). The best pervaporation selectivity was 264 ([85, 86]).

#### 1.1.11.2 Removal of Trace Water from UDMH

Traces of water can be removed from UDMH by passing the mixture through a column packed with molecular sieves. The adsorption isotherms of trace water in UDMH on 3A, 4A, and 5A molecular sieves were determined and curve-fitted by using the Langmuir equation and Freundlich equation [87]. The adsorption isotherms on 3A and 4A

molecular sieves were most consistent with results curve-fitted by the Langmuir equation. The adsorption isotherm on the 5A molecular sieve was more suitable to that curve-fitted by the Freundlich equation. The adsorption process had no influence on other contaminants, including FDMH or dimethylamine.

The isothermal adsorption data of small amounts of water in UDMH on 4A molecular sieves were measured and curve-fitted well according to the models by Langmuir and Freundlich [88]. The activation energy of water adsorption on 4A molecular sieves was  $E_a = 28.22 \text{ kJ/mol}$ . The dynamic breakthrough curves in fixed-bed columns were measured for a residence time of 60 minutes. These results can be used as the basis for the design of a full-scale adsorption process. Out-of-spec UDMH with excessive water content can be regenerated by fractionated distillation [89].

#### 1.1.11.3 Purification of UDMH

Even with the best care devoted to the manufacturing of UDMH, the carryover of some contaminants from the reaction mixture is inevitable. Other contaminants form during storage if air is not carefully excluded from the storage containers.

Charcoal that was activated by treatment with strong ammonia water, 1 mol/L  $\text{NH}_4\text{Cl}$ , and 0.5 mol/L NaOH solution or by microwave treatment could remove yellow discoloration from aged UDMH [90, 91]. The adsorption isotherm showed that the adsorption process of a yellow substance in UDMH on the activated carbon is endothermic.

### 1.2 Physical Properties of Unsymmetrical Dimethylhydrazine

The physical properties of UDMH are summarized in Table 1. There used to be several widely distributed manufacturer's marketing brochures regarding the physical properties and safe handling of UDMH [92, 93]. These are no longer available because UDMH ceased to be produced in the US. Other bibliographies and handbooks on the properties of UDMH were compiled by UDMH users or produced under US Government contracts [94–98].

#### 1.2.1 Density of UDMH

The measurements of the density of UDMH performed by various authors and organizations agreed quite well when it came to the temperature range of between 210 to 330 K. The composite smoothed data from several sources [95, 99, 100] can be expressed by the equation

$$\rho = 1.06041 - 7.7507 \times 10^{-4} T - 4.8648 \times 10^{-7} T^2$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. This is the equation used to construct the density curve in Figure 1.

**Table 1:** Physical properties of UDMH.

| Property                           | Unit                                                 | UDMH                    |
|------------------------------------|------------------------------------------------------|-------------------------|
| Molecular mass (weight)            |                                                      | 60.0986                 |
| Melting point                      | K                                                    | 215.94                  |

A simpler linear equation,

$$\rho = 1.09450 - 1.0343 \times 10^{-3}T,$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin, may be used with almost equal accuracy. Other authors obtained the following relationship for pure UDMH, reporting slightly higher densities [101]:

$$\rho = 0.4478 + 4.2160 \times 10^{-3}T - 1.028 \times 10^{-5}T^2$$

**Figure 1:** Density of liquid UDMH. (Reproduced and modified from [95].)

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. At elevated temperatures, the liquid and vapor densities converge at the critical density and critical temperature, as shown in Figure 2. Only saturated liquid and saturated vapor densities are included in this chart.

### 1.2.2 Compressibility and Sonic Velocity of UDMH

Data are available for both the isothermal and adiabatic compressibility of UDMH. Data for the isothermal compressibility are summarized in Table 2.

The adiabatic compressibility of UDMH was derived from measured sonic velocity data. The temperature dependence of the adiabatic compressibility can be expressed by the following equation:

$$\beta_a = 3.9348 \times 10^{-4} - 2.8074 \times 10^{-6} T + 5.9151 \times 10^{-9} T^2$$

where  $\beta_a$  is the adiabatic compressibility in  $\text{atm}^{-1}$  and  $T$  is the temperature in kelvin. The curve in Figure 3 was derived from this equation.

**Figure 2:** Density of UDMH saturated liquid and vapor as a function of temperature. (Reproduced and modified from [95] and [102].)

**Table 2:** Isothermal compressibility of UDMH.

| Temperature, K                        | 373                        | 403   | 433   | 463   |
|---------------------------------------|----------------------------|-------|-------|-------|
| Units                                 | Isothermal compressibility |       |       |       |
| $\text{cm}^2/\text{kg}_f \times 10^4$ | 2.049                      | 2.776 | 3.874 | 6.447 |
| $\text{m}^2/\text{N} \times 10^9$     | 2.089                      | 2.830 | 3.949 | 6.572 |

Data source: [102].

The temperature dependence of the sonic velocity of compression waves in UDMH can be expressed using the following equation:

$$c = 2582.1 - 4.4781 T$$

where  $c$  is the sonic velocity in m/s and  $T$  is the temperature in kelvin. The sonic velocity curve in Figure 4 was drawn based on this equation.

**Figure 3:** Adiabatic compressibility of liquid UDMH. (Reproduced and modified from [95].)

**Figure 4:** Sonic velocity of liquid UDMH. (Reproduced and modified from [95].)

### 1.2.3 Vapor Pressure of UDMH

The composite vapor pressure equation for UDMH, as constructed from combined data obtained by Aston [103], Barger [102], and Chang [104], is

$$\log p = 6.73578 - \frac{875.89}{T} - \frac{140001.0}{T^2}$$

where  $p$  is in mm Hg and  $T$  is in K. It represents the combined data from the three different authors with only small deviations and indicates a normal boiling point of 335.5 K (144.2°F). The curve in Figure 5 for the vapor pressure below the normal point was derived from this equation.

**Figure 5:** Vapor pressure of UDMH below the normal boiling point. (Reproduced and modified from [95].)

A more recent source [105, 106] determined the vapor pressure of UDMH as

$$\ln p = 22.394289 - \frac{6551.0134}{T} + \frac{424700.9}{T^2}$$

where  $p$  is in mm Hg and  $T$  is in K. The vapor pressure between the boiling point and the critical point can be described using

$$\log p = 4.9439 - \frac{1659.84}{T}$$

where  $p$  is in atm and  $T$  is in K [102]. This is the data illustrated in Figure 6.

**Figure 6:** Vapor pressure of UDMH above normal boiling point. (Reproduced and modified from [95].)

In general, the vapor pressure data in the range of 248 to 308 K (–25 to +35 °C) reported by Chang and Gokcen [104] are higher than those reported by Aston [103] and those for low temperatures reported by Pannetier and Mignotte [107]. At temperatures above 308 K, the data from Chang and Gokcen [104] are lower than those reported by previous authors. Vapor pressures reported by Lawrence [94] in the range of 298 K (25 °C) up to the critical point (523 K = 250 °C, 53.5 atm) for vapor pressures above one atmosphere and at the higher temperatures are suspect since these measurements were made in an apparatus that used mercury (a material which reacts with UDMH) as a confining fluid [94].

Table 3 provides a comparison of UDMH vapor pressure data from various literature sources. There is quite a bit of scatter among these data, especially at higher temperatures.

### 1.2.3.1 Vapor-Phase Composition of UDMH Mixtures

The vapor-phase compositions of UDMH/H<sub>2</sub>O mixtures are discussed in Section 2.1.2. The vapor-phase compositions of UDMH/N<sub>2</sub>H<sub>4</sub> mixtures are discussed later in this chapter (see [109]). A model was deduced from the study of the water-alkylhydrazines vapor-liquid equilibria. It represents strong interactions between molecules as chemical associations and allows one to correctly reproduce all the liquidus curves. This modeling was based on the evolution of the Raman spectra of the liquid phase. The model can also be used to reproduce the system of UDMH/water (see [110]).

**Table 3:** Comparison of UDMH vapor pressure data.

|             |     | Reference                        |                                    |                       |                              |                 |

| 423         | 150 | 9768                             | 9331                               | 13480                 | 10040                        | 19300           |

### 1.2.4 Viscosity of UDMH

Viscosity data for UDMH from Horvitz and Osborg [100] and Barger [102] have been combined in the following equation:

$$\log \mu = 0.25411 - \frac{623.532}{T} + \frac{1.811518 \times 10^5}{T^2}$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. A curve calculated from this formula is illustrated in Figure 7.

**Figure 7:** Absolute (dynamic) viscosity of liquid UDMH. (Reproduced and modified from [95].)

### 1.2.5 Surface Tension of UDMH

Knowledge of the surface tension of methylhydrazines is of both theoretical and practical interest for two reasons; **(1)** the surface tension can be used to derive parachor data and gain information on the molecular structure of these compounds and, secondly, **(2)** the design of fuel tanks for retaining fluids by capillary forces in the weightlessness of outer space requires the knowledge of the surface tension and wetting angles.

The surface tension of UDMH as a function of temperature can be expressed by the following equations [95, 111]:

$$\sigma_{\text{UDMH}} \left( \frac{\text{dyn}}{\text{cm}} \right) = 56.705 - 0.1094T$$

$$\sigma_{\text{UDMH}} \left( \frac{\text{N}}{\text{m}} \right) = 0.056705 - 1.094 \times 10^{-4} T$$

where  $T$  is the temperature in kelvin. The surface tension curve in Figure 8 was derived from this equation.

**Figure 8:** Surface tension of UDMH. (Reproduced and modified from [95].)

### 1.2.6 Thermal Conductivity of UDMH

The following linear relationship, which is more simple than the one for MMH, has been obtained for the thermal conductivity of 99.8% liquid UDMH [112]:

$$\lambda(\text{cal cm}^{-1} \text{K}^{-1} \text{s}^{-1}) = 6.7975 \times 10^{-4} - 1.0187 \times 10^{-6} T$$

$$\lambda(\text{W K}^{-1} \text{m}^{-1}) = 2.8441 \times 10^{-1} - 4.2622 \times 10^{-4} T.$$

where  $T$  is the temperature in kelvin. The thermal conductivity curve in Figure 9 was derived from this equation. At 298 K, a single data point for the thermal conductivity of liquid UDMH was reported as  $4.8 \times 10^{-4} \text{ cal s}^{-1} \text{ cm}^{-1} \text{ K}^{-1} = 2.0 \times 10^{-1} \text{ W m}^{-1} \text{ K}^{-1}$  [93]. The thermal conductivity of UDMH vapor at 0.17 atm was determined as being between 278.9 and 306.2 K using a hot-wire method [113]. Thermal conductivity was  $272, 274, 293, \text{ and } 301 \times 10^{-7} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$  at 278.9, 282.3, 302.6, and 306.2 K, respectively. A linear relationship between temperature and thermal conductivity was assumed for extrapolation purposes. This inferred  $266 \times 10^{-7} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$  and  $316 \times 10^{-7} \text{ cal cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$  at 273 and 323 K, respectively. To convert units from  $\text{cal cm}^{-1} \text{ K}^{-1} \text{ s}^{-1}$  to  $\text{W K}^{-1} \text{ m}^{-1}$ , it should be multiplied by 418.4.

**Figure 9:** Thermal conductivity of liquid UDMH. (Reproduced and modified from [95].)

### 1.2.7 Heat-Transfer Properties of UDMH

As opposed to anhydrous hydrazine, which is likely to explode during soakback and cooldown of an engine at the end of a run, UDMH can be safely used as fuel in regeneratively fuel-cooled engines [114, 115]. An excellent summary of heat flux limits of storable rocket propellants, including hydrazine, MMH, UDMH, and their mixtures, are provided in [116].

### 1.2.8 Molecular Structure of UDMH

The molecular structure of UDMH is illustrated in Figure 10.

**Figure 10:** Molecular structure of UDMH.

The following atom distances and angles of UDMH were determined from electron diffraction studies [117]:

|       |                                             |
|-------|---------------------------------------------|
| C—N   | $(7 \pm 0.03) \times 10^{-10} \text{ m}$    |
| C—N   | $\sim 1.09 \times 10^{-10} \text{ m}$       |
| N—N   | $(1.45 \pm 0.03) \times 10^{-10} \text{ m}$ |
| N—H   | $\sim 1.04 \times 10^{-10} \text{ m}$       |
| C—N—C | $110 \pm 4^\circ$                           |
| C—N—H | $110 \pm 4^\circ$                           |

In general, the more symmetrical a molecule is, the more stable it is (consider adamantane). Because the atomic weight of an  $\text{—NH}_2$  group is very similar to that of a  $\text{—CH}_3$  group, UDMH can be written as an ammonia molecule with all three hydrogens substituted by groups of similar atomic weight.

It was pointed out that this arrangement favors the possibility of resonance structures. Notably, the shorter the N—N distance ( $1.45 \times 10^{-10}$  vs.  $1.5 \times 10^{-10}$  m for  $\text{N}_2\text{H}_4$ ) the higher the N—N bond energy ( $301 \text{ kJ/mol} = 72 \text{ kcal/mol}$  instead of  $251 \text{ kJ/mol} = 60 \text{ kcal/mol}$ ), which seems to confirm this theory [118]. The N—N bond energy in UDMH has been measured and compared to that in MMH or hydrazine [119].

Bond energies are identical with dissociation energies required to break a particular bond (but there may be contributions by energy stored in other degrees of freedom of the molecule). Table 4 is a summary of bond dissociation energy (BDE) data in UDMH in comparison to other methylhydrazines. The bond lengths and angles in the molecular structure of UDMH based on Raman spectra [103] agreed with those obtained by electron diffraction [117].

**Table 4:** BDEs in UDMH in comparison to other methylhydrazines.

| Bond                                                   | Dissociation energy |            |
|--------------------------------------------------------|---------------------|------------|
|                                                        | kJ/mol              | kcal/mol   |
| <i>1,1-Dimethylhydrazine</i>                           |                     |            |
| $(\text{CH}_3)_2\text{NNH—H}$                          | 368                 | 88         |
| $(\text{CH}_3)_2\text{NNH—H}$                          | $356 \pm 21$        | $85 \pm 5$ |
| $\text{H}_2\text{NN}(\text{CH}_3)\text{—CH}_3$         | 377                 | 90         |
| $\text{H}_2\text{N—N}(\text{CH}_3)_2$                  | $156 \pm 21$        | $38 \pm 5$ |

Data sources: [118, 120, 121].

Entropies calculated and compared to those expected from Raman data indicated that a *trans* configuration is very unlikely for UDMH. Other electron-diffraction measurements for UDMH vapor reported an N—N distance of  $1.437 \times 10^{-10}$  m, an N—C distance of  $1.469 \times 10^{-10}$  m, a  $\angle\text{CNC}$  angle of  $111.2 \pm 0.5^\circ$ , and an  $\angle\text{NNC}$  angle of  $108.2 \pm 0.4^\circ$  [122]. The rotation around the N—N bond was studied using MNDO/2 and *ab initio* methods. The skew shape of UDMH was supported by the photoelectron spectra of UDMH vapor [123, 124]. An electron diffraction spectroscopy study of the molecular structure of SDMH and UDMH provided exact atomic distances and bond angles [117].

The molecular structures of UDMH and other hydrazines have been modeled in an effort to predict the enthalpies of formation of the molecules in the vapor state and to identify the weak links in the molecule (those that break first when the molecule is heated).

Based on quantum mechanical and molecular mechanics (MM3) studies of hydrazines, the N—N bond lengths are much longer in the *syn* and *anti* conformations of UDMH than in the *gauche* conformation [125].

Calculations in a combined density functional theory (DFT, B3LYP) and G2MP2 theoretical study resulted in enthalpies of formation ( $H^\circ_f$ ) and bond dissociation enthalpies (BDE) for UDMH of  $80 \pm 4$  kJ/mol and  $259 \pm 12$  kJ/mol, respectively [126].

Improved molecular models for hydrazine, methylhydrazine, and 1,1-dimethylhydrazine were developed to study the fluid-phase behavior of these compounds [127, 128]. A parameterization of classical molecular interaction models was carried out by using quantum chemical calculations and subsequent fitting to experimental vapor pressure and saturated liquid density data. To validate the molecular models, vapor-liquid equilibria for the pure hydrazines and binary hydrazines mixtures with water or ammonia were calculated and compared with available experimental data. In addition, the Henry's-law constant for the physical solubility of argon, nitrogen, and carbon monoxide in liquid UDMH was computed. In general, the simulation results were in good agreement with the experimental data. The computed results for saturated densities, vapor pressure, and heat of vaporization were compared to the available experimental data and the simulation results published by Gutowski et al. [129]. The saturated liquid density based on the model by Gutowski et al. [129] followed an opposite trend relative to hydrazine and methylhydrazine, i.e., the density from the simulation was larger than that reported in the experiment. Over the temperature range of 273 to 339 K, the values by Gutowski were in excellent agreement with the experiment, being only slightly higher (0.5 to 1.7%). Notably, at higher temperatures, the density deviations increased. The Elts et al. [127] model reported average deviations from the experimental saturated liquid density of about 1.3% over the whole temperature range. For the vapor pressure, the data derived from the Elts et al. model deviated from the experiment only by about 3.7%, while the values reported by Gutowski et al. [129] underestimated the experimental vapor pressure by more than 80% above 340 K. The enthalpy of vaporization predicted by Gutowski et al. [129] at 298 and 339 K were higher than the experimental values by around 8 kJ/mol, which is 24% in relative terms. For the Elts et al. [127] model, these deviations were minor, yielding a mean unsigned error of about 1.0%.

Composite *ab initio* methods and DFT methods were used to calculate accurate BDEs of UDMH [130]. It was found that the results calculated by composite *ab initio* methods were in good agreement with literature values for all other types of bonds of the molecule except the N—C bond. Of the results calculated using DFT methods, the Boese–Martin for Kinetics (BMK) method produced results very similar to composite *ab initio* methods. For the N—H and C—H bonds, the B3P86 method performed slightly

better than the BMK method, while the B3LYP data set generally underestimated the BDE of UDMH. Results from restricted open-shell-method calculations were superior to an unrestricted method due to spin contamination.

Full geometrical optimizations of the 1,1-dimethylhydrazine molecular structure have been carried out by quantum-mechanical methods Restricted Hartree-Fock (RHF), Becke, 3-parameter, Lee–Yang–Parr (B3LYP) (B3LYP), and Møller-Plesset perturbation theory (MP2), respectively, and the optimal geometric structure parameters have been obtained [131]. The predicted structure parameters were compared to experimental results. Except for two predicted parameters ( $\angle\text{C–N–N–H}$  dihedral angle and C–H bond length, which showed smaller values), all others agreed well with the experimental results. All these calculations indicated a *gauche* conformation. The predicted N–N bond length was about 0.143 nm and the C–N bond length was about 0.147 nm. The bond angles of  $\angle\text{N–N–C}$  and C–N–C were about 112 and 113.8°, respectively. The  $\angle\text{C–N–N–H}$  dihedral angle was about 86°.

Dimethyldiazene is an important intermediate product in the reaction of UDMH and  $\cdot\text{OH}$ . A DFT calculation was performed to study the reaction mechanism of dimethyldiazene formation [132]. All transition states were characterized by one imaginary frequency on the potential energy surface. The energy curve of the reaction was obtained using vibrational energy calculations.

Full geometrical optimizations of UDMH structures have been carried out to study the nucleophilicity difference between  $-\text{NH}_2$  and  $-\text{N}(\text{CH}_3)_2$  of the two halves of the molecule [133]. The calculated results of nucleophilicity by molecular orbital theory agreed with the experimental results, showing that the nucleophilicity of  $-\text{N}(\text{CH}_3)_2$  is stronger than that of  $-\text{NH}_2$ .

### 1.2.9 Optical Properties of UDMH

The optical properties of UDMH and other methylhydrazines are important for analytical applications, verifying the purity of propellant before it is being loaded into spacecraft or missiles, and detecting the presence of leaked UDMH vapors in areas where it does not belong and constitutes a hazard to both equipment and personnel. Spectra of UDMH enabled us to better understand the structure of this molecule and derive thermochemical properties that are important for its use as a rocket propellant.

#### 1.2.9.1 UV Absorption Spectra of UDMH

Vacuum UV (VUV) absorption coefficients for hydrazine, MMH, and UDMH were measured from 115 to 185 nm to determine the interference of leaked propellants with UV sensors in space applications [134]. VUV absorption coefficients for  $\text{N}_2\text{H}_4$ ,  $\text{CH}_3\text{HNNH}_2$ , and  $(\text{CH}_3)_2\text{NNH}_2$  were measured for wavelengths between 115 and 185 nm with an estimated experimental error of  $\pm 15\%$ . The measurements were made in a hydrazine-compatible flow-cell apparatus at room temperature.

For the UV absorption of UDMH at 213.9 nm, a UV absorption cross-sections of  $\sigma = 399.9 \times 10^{-20} \text{ cm}^2/\text{molecule}$  was assumed for UDMH photolysis and autoxidation studies in the atmosphere [135, 136].

### 1.2.9.2 Infrared Spectra of UDMH

The IR and Raman spectra of liquid and gaseous UDMH between 700 and 1600  $\text{cm}^{-1}$  for the gas phase and between 700 and 3500  $\text{cm}^{-1}$  for the liquid phase and of trimethylhydrazine have been measured [137, 138]. The wavenumbers and intensity of IR and Raman lines are listed in Table 5.

**Table 5:** Infrared and Raman band wavenumbers for UDMH spectra.

| Infrared                            |                |           |                                     |           |           | Raman                          |                    |              |                   |

Data source: [138].

The infrared and Raman fundamental vibration band assignments for UDMH are listed in Table 6. Some unassigned frequencies were later identified as combinations of assigned frequencies (wavenumbers). The line at  $282\text{cm}^{-1}$  in the Raman spectrum of UDMH is probably due to internal rotation. Similar assignments were made for a spectrum of trimethylhydrazine.

The IR spectra of MMH, UDMH, SDMH, formaldehyde-*N,N*-dimethylhydrazone,  $\text{H}_2\text{C}=\text{N}-\text{N}(\text{CH}_3)_2$ , trimethylhydrazine, and tetramethylhydrazine are contained in a catalog of IR spectra for qualitative analysis of gases [139]. This useful summary also includes the IR spectra of 30 other compounds found in propellant mixtures.

The preliminary band assignments by Shull et al. [139] were superseded by more accurate measurements by Durig and Harris [140] reported 14 years later. The IR spectra of UDMH and  $\text{D}_2\text{NN}(\text{CH}_3)_2$  have been recorded in both liquid and vapor states from  $33$  to  $4000\text{cm}^{-1}$  [140], as demonstrated in Figures 11 and 12.

In addition, the spectra of deuterated UDMH and IR spectra of solid UDMH were recorded as being between  $33$  to  $4000\text{cm}^{-1}$ . Raman spectra of liquid UDMH between  $200$  to  $4000\text{cm}^{-1}$  could be correlated with the IR spectra recorded. The spectra were interpreted based on  $C_1$  symmetry. All 30 vibrations were assigned based on intensity, position, and isotope shift. The band assignments in Table 7 supersede the older assignments listed in Table 6.

The methyl torsional fundamentals were identified and found to correspond to a barrier hindering the free rotation of the methyl group that was equivalent to  $19.6\text{kJ/mol}$  ( $4.69\text{kcal/mol}$ ). The amino group free rotation is restrained by

**Figure 11:** Infrared spectrum of liquid UDMH. (Reprinted and modified from [140], with the permission of ©1969 AIP Publishing.)

**Figure 12:** Infrared spectrum of UDMH vapor. (Reprinted and modified from [140], with the permission of ©1969 AIP Publishing.)

a barrier of 13.4 kJ/mol (3.2 kcal/mol). Individual vibration assignments in UDMH were considerably more complex than the MMH spectrum analyzed before it. Based on the spectroscopic measurements of vibrations and inertia, thermodynamic functions of the *gauche* conformation were calculated from 200 to 3000 K. At 298.16 K,  $S^0$  was 296.3 J mol<sup>-1</sup> K<sup>-1</sup> (70.82 cal mol<sup>-1</sup> K<sup>-1</sup>),  $-(F^0 - E_0^0)/T$  was 239.8 J mol<sup>-1</sup> K<sup>-1</sup> (57.31 cal mol<sup>-1</sup> K<sup>-1</sup>),  $(H^0 - E_0^0)/T$  was 56.5 J mol<sup>-1</sup> K<sup>-1</sup> (13.51 cal mol<sup>-1</sup> K<sup>-1</sup>), and  $C_p$  was calculated to be 90.33 J mol<sup>-1</sup> K<sup>-1</sup> (21.59 cal mol<sup>-1</sup> K<sup>-1</sup>).

Several of the 30 fundamental vibrations ascribed to the UDMH molecule by Shull et al. [138] had to be reassigned because of the more recent data supplied by Durig and Harris [140]. These data, in turn, have been superseded. Further to this, some of the contradictions may have been eliminated by later examinations by Anthoni, Larsen, and Nielsen [141]. They were able to assign most of the 30 possible funda-

**Table 7:** Fundamental vibration band assignments for UDMH spectra.

| Number     | Approximate description of vibration       | Wavenumber, cm <sup>-1</sup> |
|------------|--------------------------------------------|------------------------------|
| $\nu_1$    | NH <sub>2</sub> anti-symmetric stretching  | 3338                         |

mental vibrations. Of these, 21 belong to the (CH<sub>3</sub>)<sub>2</sub>N group, three to the NH<sub>2</sub> group, and six arise from motions of these two groups in relation to each other. Only three strong bands were left unassigned. These are most likely skeletal stretching vibrations. Some assignments could be linked by similarity with bands already assigned in organic amines which also contain the dimethylamino group.

Variable temperature (168 to 123 K = -105 to -150 °C) studies of the infrared spectra (3500–400 cm<sup>-1</sup>) of UDMH in liquid krypton provided no convincing spectral evidence for the *trans* conformer, which was expected to be at least 600 cm<sup>-1</sup> less stable than the *gauche* form [142]. The structural parameters, dipole moments, conformational

stability, vibrational frequencies, and infrared and Raman intensities have been predicted using MP2/6-31G(d) *ab initio* calculations. The predicted IR and Raman spectra were compared to the experimental spectra. The adjusted  $r_0$  parameters from MP2/6-311+G(d,p) calculations were compared to those reported from an electron diffraction study. The energy differences between the *gauche* and *trans* conformers have been obtained using MP2 *ab initio* calculations and DFT by using B3LYP method calculations from a variety of basis sets. All these calculations indicated an energy difference of 650–900 cm<sup>-1</sup>, with the B3LYP calculations predicting the larger values. *Ab initio* MP2/6-31G(d) calculations predicted the barrier to internal rotation by the independent rotor model of the inner methyl group to have a value of 1812 cm<sup>-1</sup> and that of the outer one to have a value of 1662 cm<sup>-1</sup>. These values agreed well with the experimentally determined values of 1852 ± 16 and 1558 ± 12 cm<sup>-1</sup>, respectively, which were gained from a fit of the torsional transitions with the coupled rotor model.

It is very important to identify contaminants in UDMH by IR spectroscopy. Contaminants may have been introduced while making UDMH or during storage, most often by autoxidation if air has intruded into the storage container.

One of the common autoxidation products of UDMH is FDMH. Its IR spectra have been analyzed so that it can be better identified when it is encountered as a contaminant in UDMH. The IR spectrum of FDMH, (H<sub>3</sub>C)<sub>2</sub>NN=CH<sub>2</sub>, has been measured as being between 200 and 3400 cm<sup>-1</sup> in the gaseous state and between 140 and 3400 cm<sup>-1</sup> at liquid nitrogen temperatures [143]. A comparison of the vibrational spectra in the solid and fluid states indicated that the molecule exists in only one conformer in all three physical states. The Raman spectra of the gas, liquid, and solid have also been recorded. Because of the number of polarized Raman lines, the vibrational spectra have been interpreted in terms of C<sub>1</sub> symmetry and vibrational assignments were presented based upon the observed band positions, intensities, and group frequency considerations.

Because of the need for a controlled environment, atmospheric studies of homogeneous vapor autoxidation of UDMH in the air must be conducted in laboratory chambers with non-reactive walls. It has been noted that much of the oxidation occurs heterogeneously on the walls of these chambers and it was difficult to eliminate wall effects. The IR spectra of adsorbed UDMH on chamber materials (silica, silica-alumina, and alumina) were recorded to find inert chamber materials. Diffuse reflectance spectroscopy of hydrazines adsorbed on silica, silica-alumina, and alumina indicated that the primary surface-UDMH interaction is hydrogen bonding [144–146]. In the adsorbed methylhydrazines, the C–H stretching and methyl deformation modes were shifted to higher frequencies by 10 to 20 cm<sup>-1</sup> as a result of electron density changes on the adjacent nitrogen atom. Those weakened bonds make the molecules more susceptible to autoxidation.

The IR spectra of normal UDMH, (CH<sub>3</sub>)<sub>2</sub>NNH<sub>2</sub>, and two isotopomers, (CD<sub>3</sub>)<sub>2</sub>NNH<sub>2</sub> and (CH<sub>3</sub>)<sub>2</sub>NND<sub>2</sub>, have been recorded as being in the region between 100 and 600 cm<sup>-1</sup> [147]. Very rich and complex spectra were obtained and an interpretation of the spectra

arising from the two methyl torsional modes of the deuterated compound was carried out using a semi-rigid model. The resulting potential functions for the three molecules were compared to each other. *Ab initio* gradient calculations were carried out at various levels such that the structural parameters, conformational stability, and three-fold barriers to internal rotation could be determined. The *gauche* conformer was calculated to be more stable than the *trans* form by  $783\text{ cm}^{-1}$  ( $9.37\text{ kJ/mol} = 2.24\text{ kcal/mol}$ ). Isomeric 1,1- and 1,2-disubstituted hydrazines can be readily distinguished by examination of the N–H stretching frequencies in the IR spectra of their hydrochloride salts [148].

### 1.2.9.3 Raman Spectra of UDMH

Some Raman spectra data for UDMH have already been discussed in previous sections regarding the IR spectra of UDMH (see [149]). The Raman spectrum of liquid UDMH is shown in Figure 13.

**Figure 13:** Raman spectrum of liquid UDMH. (Reprinted and modified from [140], with the permission of ©1969 AIP Publishing.)

### 1.2.9.4 Index of Refraction of UDMH

The index of refraction data for UDMH is listed in Table 8.

**Table 8:** Index of refraction data for UDMH.

| Compound              | Temperature, K | $n_D$                | References |
|-----------------------|----------------|----------------------|------------|
| 1,1-Dimethylhydrazine | 298.1          | 1.4051               | [150]      |
|                       | 298.1          | 1.4055               | [151]      |

<sup>a</sup>Wavelength 589.3 nm

### 1.2.10 Photoelectron and XPS Spectra of UDMH

The unimolecular dissociation of UDMH ions was studied by threshold photoelectron-photoion coincidence spectroscopy [153]. Time-of-flight distributions and breakdown curves were recorded in the photon energy range of 9.5–10.4 eV. The appearance energies of the fragment ions were extracted by modeling the experimental data with a rigid activated complex theory. It was found that the data could be well-reproduced with a single transition state for each dissociation channel if two different H-loss channels were assumed; one corresponding to a C–H and the other to a N–H bond dissociation. Once the appearance energies were established, heats of formation of the fragment ions could be derived. The enthalpy of formation of the neutral molecule was computed by applying composite *ab initio* methods on a series of isodesmic reactions between methyl hydrazines and methyl-amines. The 298 K enthalpy of formation of UDMH vapor was calculated to be  $79.7 \pm 2.2$  kJ/mol, which is within the experimental error of the value of  $83.3 \pm 3.6$  kJ/mol, as reported by Donovan et al. [154]. The adiabatic ionization energy of UDMH was measured to be  $7.29 \pm 0.04$  eV.

The He I photoelectron spectra of UDMH have been measured and CNDO/2 calculations have been carried out [124]. It has been found that non-bonding splittings in the photoelectron spectra are well reproduced by CNDO/2 calculations with *gauche* forms. The results of conformation modeling were supported by published conformational studies. The first and second bands are due to the methylated and unmethylated nitrogen lone pairs, respectively. The third bands are attributed to the N–N bonding orbitals. The rest of the photoelectron spectra up to 18 eV can be explained in terms of other p-type orbitals (C–N bonding, CH<sub>3</sub> pseudo  $\pi$ , and NH<sub>2</sub> pseudo  $\pi$ ).

### 1.2.11 Thermodynamic Properties of UDMH

Thermodynamic properties of UDMH have been derived from spectroscopic or calorimetric data (see [155]).

#### 1.2.11.1 Heat Capacity of UDMH

The heat capacity data of liquid UDMH from [103] and Rocketdyne [156, 157] have been curve-fitted and may be calculated to  $\pm 1.3\%$  by

$$\begin{aligned}c_p(\text{cal g}^{-1} \text{K}^{-1}) &= 0.4071 + 8.838 \times 10^{-4} T \\c_p(\text{J g}^{-1} \text{K}^{-1}) &= 1.7033 + 3.6978 \times 10^{-3} T.\end{aligned}$$

At 298 K,  $C_p$  is  $164.0 \text{ J mol}^{-1} \text{K}^{-1}$  ( $39.2 \text{ cal mol}^{-1} \text{K}^{-1}$ ).

Other sources [108] have derived equations for the heat capacity of solid, liquid, and vapor UDMH as

$$\begin{array}{ll} \text{Solid} & c_p = 13.09 - 1.585 \times 10^{-2}T + 2.742 \times 10^{-4}T^2 \\ \text{Liquid} & c_p = 28.88 + 3.536 \times 10^{-2}T - 2.421 \times 10^{-6}T^2 \\ \text{Ideal Gas} & c_p = -0.05791 + 9.334 \times 10^{-2}T - 5.129 \times 10^{-5}T^2 \end{array}$$

where  $c_p$  is the heat capacity in  $\text{cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin.

#### 1.2.11.2 Enthalpy of Formation of UDMH

For UDMH, heats of combustion have been reported by both Aston, Rock, and Isserow 1952 [158] and Donovan, Shomate, and McBride 1960 [154]. The heat of combustion of UDMH was measured at 303 K and found to be 1980.5 kJ/mol (473.356 kcal/mol) [159] or 1977.6 kJ/mol = 472.648 kcal/mol [158]. The value by Aston et al. [158] has to be corrected to 298 K like the MMH data previously discussed in this chapter. The corrected heat of combustion at 298 K is 1982 kJ/mol = 473.701 kcal/mol. The enthalpy of formation of liquid UDMH derived from this number is  $(\Delta H)_f^{298} = +51.63 \text{ kJ/mol} = +12.339 \text{ kcal/mol}$ . The enthalpy of formation of UDMH vapor is  $+83.3 \pm 3.6 \text{ kJ/mol}$ . The heat of combustion reported by Donovan, Shomate in 1960 was  $1980.2 \pm 1.8 \text{ kJ/mol} = 473.28 \pm 0.43 \text{ kcal/mol}$  [154]. Other reported values for the heat of combustion of UDMH are 1983.7 kJ/mol (474.11 kcal/mol) [93].

#### 1.2.11.3 Enthalpy of Fusion of UDMH

The heat of fusion of UDMH, when corrected for pre-melting, was  $10.0726 \pm 0.0063 \text{ kJ/mol}$  ( $2.4074 \pm 0.0015 \text{ kcal/mol}$ ) and  $215.951 \pm 0.005 \text{ K}$  at the triple point [103, 160]. The decreasing molar heat of the fusion of methylhydrazines with progressive methylation is an indication of reduced hydrogen bonding in the series  $\text{N}_2\text{H}_4$ , MMH, and UDMH.

#### 1.2.11.4 Enthalpy of Vaporization of UDMH

The heat of vaporization of UDMH was not only derived from the vapor pressure curve; it was also directly measured [160]. The average of five determinations for UDMH gave  $(\Delta H)_{\text{vap}}^{298} \text{ UDMH} = 35.00 \pm 0.07 \text{ kJ/mol} = 8.366 \pm 0.016 \text{ kcal/mol}$  when measured [103] or  $32.8 \text{ kJ/mol} = 7.844 \text{ kcal/mol}$  when calculated [104]. From the equation

$$\log p = 6.73578 - \frac{875.89}{T} - \frac{140001.0}{T^2}$$

a heat of vaporization at the normal boiling point of  $7.797 \text{ kcal/mol} = 32.62 \text{ J/mol}$  was calculated. The Trouton constant of UDMH is 23.2.

Attempts to predict vapor pressure and enthalpy of vaporization of UDMH from theoretical computations have not always produced accurate results [127].

### 1.2.11.5 Entropy of UDMH

Aston et al. reported an ideal gas entropy of UDMH vapor at 298.16 K that was equal to  $72.82 \pm 0.20$  e.u. [103]. This was calculated using calorimetric data. A value of 70.70 e.u. was reported for the *trans* form and a value of 72.30 e.u. was reported for the *gauche* form. These were calculated using spectroscopic and molecular structure data. Since the *trans* form has higher energy than the *gauche* form, the *trans* form exists only in negligible quantities at room temperature. Therefore, the agreement between the values of entropy calculated from the two sets of data is very good. The entropy of liquid UDMH was listed as  $\Delta S_{298} = 47.86 \text{ cal mol}^{-1} \text{ } ^\circ\text{C}^{-1}$ .

### 1.2.12 Solubility of Pressurant Gases in Dimethylhydrazine

The solubility of gases in hydrazine(s) is of interest with regard to rocket propellants. In many cases, at least for small engines, the propellants are fed into the combustion chamber by a pressurant gas (usually nitrogen or helium). Unless a gas-tight, impermeable diaphragm is employed, the fuels become saturated with the pressurant gas. Heat-transfer characteristics of the gas-saturated liquids are significantly different from those of the pure liquid because dissolved gas bubbles are released prematurely, thus blocking effective heat transfer and sometimes causing the rocket chamber wall to burn out. Release of dissolved gasses and loss of thermal margin causes two-phase flow. Two-phase flow has a higher pressure drop than clean single-phase flow. Solubility-pressure relationships are governed by Henry's law

$$X = KP$$

where  $X$  is the mol fraction of dissolved gas,  $P$  is the partial pressure of the gas, and  $K$  is the solubility constant. If the pressure is entered in units of atmospheres, then the unit of  $K$  is  $\text{atm}^{-1}$ .

The solubility of common pressurant gases (nitrogen, argon, helium) in methylhydrazines has been determined by Chang, Gokcen, and Poston [161–163]. The equilibrium constant  $K_i$  for the pressurant gas equilibrium between the gas phase and the dissolved state is the mol fraction of solute  $i$  divided by its partial pressure  $P_i$  over the equilibrated solution. Its temperature dependence can be expressed by

$$\log K_i = \frac{A}{T} + B$$

where  $A$  and  $B$  are constants and  $T$  is the absolute temperature. Table 9 provides a summary of  $A$  and  $B$  constants for three different gases dissolved in various hydrazines and one hydrazine blend. Figure 14 shows the same data in graphic form (see [164]).

**Table 9:** Solubility of pressurant gases in UDMH in comparison to other hydrazines.

| Gas             | Propellant                    | A    | B      | Solubility at 101 kPa, ppm by wt. |       |
|-----------------|-------------------------------|------|--------|-----------------------------------|-------|
|                 |                               |      |        | 273 K                             | 298 K |
| He              | UDMH                          | -461 | 2.3410 | 4.5                               | 6.2   |
| N <sub>2</sub>  | UDMH                          | -175 | 2.8275 | 154                               | 174   |
| Ar              | UDMH                          | -52  | 2.8351 | 440                               | 456   |
| For comparison: |                               |      |        |                                   |       |
| He              | N <sub>2</sub> H <sub>4</sub> | -275 | 0.7387 | 0.5                               | 0.6   |
| N <sub>2</sub>  | N <sub>2</sub> H <sub>4</sub> | -516 | 2.5322 | 4.4                               | 6.3   |

### 1.2.13 Electrical Properties of UDMH

Electrical properties summarized in this section include electrical conductivity, dielectric constant, dipole moment, dissociation constant, and magnetic properties. Measurement of the movement and orientation of ions and dipoles in hydrazine derivatives is a fascinating field of study that compares the behavior of UDMH to that of water, hydrazine, and other non-aqueous solvents.

### 1.2.14 Dipole Moment of UDMH

Calculated dipole moments (in Debye units) were 2.93 (UDMH) and 0.06 (SDMH) [165]. Reported measured dipole moments of UDMH vapor are 1.68 D [122] or 1.72 D [166]. Dipole moment data indicated that molecules of  $R_2NNHR'$  ( $R, R' = \text{Me, H; Et, H; Et, Et; Me, Me}_2\text{CH; Me, Me}_3\text{Si; Et}_3\text{Si}$ ) possess the *gauche* conformation. In the Si-containing compounds, this conformation is stabilized by  $p\pi$ - $d\pi$  conjugation.

### 1.2.15 Critical Point Data of UDMH

Critical constants for UDMH are summarized in Table 10. Most of these data were calculated from other physical and thermodynamic properties measured under non-critical conditions. UDMH and other hydrazines are certain to decompose before critical point conditions can be achieved while heating up.

**Table 10:** Critical constants of UDMH in comparison to MMH and hydrazine.

| Compound        | Critical temperature |     | Critical pressure |      | Critical density  | References |
|-----------------|----------------------|-----|-------------------|------|-------------------|------------|
|                 | K                    | °C  | MPa               | atm  | g/cm <sup>3</sup> |            |
| UDMH            | 522                  | 249 | 6.06              | 59.8 | —                 | [103]      |
| UDMH            | 523                  | 250 | 5.4               | 53.3 | 0.275             | [102]      |
| For comparison: |                      |     |                   |      |                   |            |
| Hydrazine       | 653                  | 380 | 0.2307            | 2.28 | —                 | [167]      |
| Hydrazine       | 653                  | 380 | 1.469             | 14.5 | —                 | [168]      |
| MMH             | 567                  | 294 | 8.1               | 80   | 0.17              | [169]      |
| MMH             | 585                  | 312 | 8.21              | 81   | 0.29              | [111, 170] |
| MMH             | 530                  | 257 | 7.6               | 75   | —                 | [160]      |

### 1.2.16 Physical Properties of UDMH Salts

UDMH forms monobasic and dibasic salts with strong mineral acids. There are no industrial applications of UDMH salts. Like UDMH nitrate, they are mostly unwanted contaminants that may form in NTO/UDMH thrusters from the trickle volume of unburned propellants trapped in the injector after the engine shuts down and combustion has ceased. The physical properties of UDMH salts are summarized in Table 11.

**Table 11:** Physical properties of UDMH salts.

| Compound                                          | Gross formula                                                               | Melting point |         | References |
|---------------------------------------------------|-----------------------------------------------------------------------------|---------------|---------|------------|
|                                                   |                                                                             | °C            | K       |            |
| UDMH•H <sub>2</sub> C <sub>2</sub> O <sub>4</sub> | C <sub>4</sub> H <sub>10</sub> N <sub>2</sub> O <sub>4</sub>                | 143           | 416     | [171]      |

### 1.3 Chemical Properties of Unsymmetrical Dimethylhydrazine

1,1-Dimethylhydrazine is a colorless and fishy-smelling liquid that can be stored indefinitely at room temperature if no ambient is allowed to leak in. UDMH is miscible in all proportions with water, hydrazine, or ammonia, however, it is not miscible with kerosene. Solutions of UDMH in water are strongly basic. If UDMH is stored in contact with air, it will both autoxidize, thus quickly leading to discoloration by becoming intensely yellow, will absorb moisture, and will also absorb carbon dioxide. Salts formed by reactions between UDMH and carbon dioxide, and their corrosion products in contact with metals, are not totally soluble in UDMH and may precipitate and clog orifices and filter screens.

#### 1.3.1 Thermal Decomposition of UDMH

The pattern of thermal decomposition of UDMH is even more complex than that of MMH or hydrazine. The thermal decomposition of UDMH has not been the focus of practical interest in the same way as MMH or hydrazine. Although UDMH has been considered a monopropellant, there is no practical way to put it to use. Gas generators in Titan-II and Russian missiles operate on fuel-rich bipropellant mixtures and the hot gas products are used to drive turbines that drive both propellant pumps. Therefore, while there is UDMH decomposition taking place, it is driven by partial combustion. The main advantage of UDMH as a monopropellant would be its low freezing point, making tank, line, and valve heaters in some satellites unnecessary. One big problem with UDMH decomposition is soot formation; this would inactivate a catalyst and plug thermal bed supports and injector orifices.

UDMH is not typically used as a monopropellant since its decomposition is very sooty and results in the formation of toxic hydrogen cyanide. Soot accumulation and cyanide adsorption would quickly foul and poison all catalyst beds. UDMH decomposition on metals is mostly of interest because unwanted, premature UDMH decomposition may occur in hot inlet sections of bipropellant thrusters using UDMH fuels or for the disposal of unwanted surplus UDMH. For bipropellant thrusters, metals found to be catalytic for UDMH decomposition should be avoided in places where the fuel might

get hot (e.g., injectors, regenerative cooling channels, heat exchangers). It appears that on one of the Apollo moon landings, UDMH decomposition from the Aerozine-50 propellant blend caused by heat soaking back from the hot engine momentarily caused a red light to flash after the lander engine was shut down.

This section on the decomposition (autodecomposition) of UDMH overlaps and somewhat duplicates information provided in a previous section in this chapter (regarding the safety properties of UDMH), however, it emphasizes the kinetics of the reaction and not just the temperature and pressure conditions under which it starts. Thermal decomposition kinetics studies were performed under both static and dynamic flow conditions.

### 1.3.1.1 Thermal Decomposition of UDMH in Static and Flow Reactors

The thermal decomposition of UDMH was studied in an isothermal-flow reactor made from Pyrex tubing [173]. The decomposition started at 673 K (400 °C). The overall first-order reaction rate constant was found to be equal to

$$k = 10^{7.83 \pm 0.2} \exp\left(\frac{28680 \pm 680 \text{ cal}}{RT}\right) \text{ s}^{-1}$$

and the activation energy was 111.6 kJ/mol (28.68 kcal/mol). The products of decomposition were analyzed and found to consist mainly of methane and nitrogen with small amounts of hydrogen and traces of ammonia, dimethylamine, ethane, propane, and methylene methylamine. No cyanide was observed in this study, as opposed to results by other investigators. It was concluded that the decomposition takes place in the gas phase because it did not show a marked dependence on the surface: volume ratio of the reactor.

The thermal decomposition of hydrazine, MMH, and UDMH was studied by the toluene carrier method [174]. The homogeneous decomposition of UDMH in toluene can be accounted for by the mechanism:

with toluene acting as a scavenger for amino radicals. The fate of the dimethylamino radicals is unknown but they do not form DMA in this system. The rate constant was found to be independent of toluene pressure, contact time, reactant pressure, or surface: volume ratio:

$$\log k = 13.22 - \frac{49600}{2.3RT} \text{ s}^{-1}$$
